regulatory permitting process to determine whether mines will cause exceedances of ambient air standards or PSD increments.

Gaussian Models

There are many different air quality models, but the most frequently used models employ a Gaussian formula as the governing equation to predict pollutant concentrations. This equation imposes a Gaussian or normal distribution of pollutant concentration about the centerline of the pollution plume.

A simplified version of the Gaussian equation that predicts the ground level pollution concentrations at a location x meters downwind and y meters crosswind of an elevated pollution point source is (Turner, 1970):

$$C(x, y, 0, H) = \frac{Q}{\pi \sigma_y \sigma_z u} \exp \left[-\frac{1}{2} \left(\frac{y}{\sigma_y} \right)^2 \right] \exp \left[-\frac{1}{2} \left(\frac{H}{\sigma_z} \right)^2 \right] \quad (1)$$

where C is the pollution concentration, g/m^3 ; Q is the pollutant emission rate, g/s ; σ_y is the standard deviation of concentration in the crosswind direction, m; σ_z is the standard deviation of concentration in the vertical direction, m; u is the mean wind speed, m/s; y is the distance from the plume centerline to the point predicted concentration (measured perpendicular to the plume centerline), m; and H is the height of the plume above ground level, m.

A computerized Gaussian air quality model solves Eq. 1 repeatedly for each pollutant source and each receptor (the

location where an ambient pollution concentration is to be computed) that the model user requests. To compute the impact of a surface mine on ambient TSP concentrations, for example, one would input information about all particulate matter emitting activities and specify the location of receptors that were of interest. Using meteorological data (wind direction, wind speed, atmospheric stability, temperature) provided by the modeler, the model computer program would sum the computed concentration contribution from each source at all of the receptors. Very often model receptors are located in a uniform array in the vicinity of a mine so that the resulting grid of predicted pollutant concentrations can be used to draw contours of equal concentration.

Although it is not necessary to have a detailed understanding of the inner workings of Gaussian computer models, a familiarity with certain model characteristics is helpful in choosing models and in evaluating model results. The most important characteristics are (Anon., 1982a):

Dispersion Coefficient: Pollutants in the atmosphere are dispersed and diluted by the turbulent motion of the air. Highly turbulent or unstable atmospheres tend to mix pollutants with clean air rapidly so that pollutant concentrations decrease promptly with downwind distance from the source. In stable atmospheres less mixing occurs and pollutant concentrations along the plume centerline remain higher. The stability of the atmosphere, measured by wind direction fluctuations or inferred from vertical temperature data, is generally divided into six categories ranging from very unstable to very stable (class A to F). The Gaussian models take into account the varying degrees of turbulence by means of the σ_y and σ_z dispersion coefficients in Eq. (1). Values of σ_y

Table 13. Emission Factors for Heavy Duty Diesel Equipment Operation (Pounds of Pollutant Per Gallon of Fuel Consumed)*

Pollutant	Wheeled dozer	Scraper	Grader	Front-end loader	Haul Truck
Carbon monoxide	0.123	0.085	0.055	0.099	0.123
Hydrocarbons (VOC)	0.013	0.019	0.013	0.043	0.013
Nitrogen oxides	0.286	0.259	0.254	0.321	0.286
Sulfur dioxide	0.031	0.031	0.031	0.031	0.031
Particulate	0.015	0.027	0.022	0.029	0.018

* Metric equivalent: lb/gal \times 119.826 4 = kg/m³.

and σ_z are derived from empirically determined equations for each of the six stability categories.

However, the values of the dispersion coefficients used in most models differ depending upon whether the coefficients were meant to apply in urban areas or rural areas. Obviously, for most surface mining applications, models that employ rural dispersion coefficients should be used.

Source Configuration: Eq. (1) yields pollutant concentration downwind of a source whose emissions come from a discrete, infinitesimally small point. This point source equation simulates dispersion from surface mining sources small enough to be reasonably idealized as a point, such as a thermal dryer stack or the exhaust vent from a baghouse. But many mining activities emit pollutants from a long linear configuration (e.g., a haul road), or from a large area (e.g., wind erosion from exposed areas). These sources, called line sources and area sources, are best modeled by variations of Eq. (1) that properly account for the area extent of the emitting source. Some dispersion models include these variations. One of the first tasks in modeling the ambient pollutant concentrations from a surface mine is to categorize each source as a point, a line, or an area idealization.

Time Interval: The Gaussian equation applies only to *steady-state* situations in which none of the important variables (wind direction, wind speed, etc.) change with time. It is also only strictly applicable for flat terrain. For modeling very short time intervals (on the order of 1 hr) it is often reasonable to assume that time-dependent variables remain constant. But to simulate pollution dispersion over longer periods of time, two methods of extending the time scale are used. The first method breaks up the desired time interval into individual, sequential 1-hr increments, models each hour separately, then averages the long-term pollutant concentration at each receptor. Using this hour-by-hour approach, an annual average concentration would be computed by separately calculating concentrations for each of 8760 hr in a year and then averaging them. The second means of extending the steady-state Gaussian equation to longer time intervals is to group each of the time-dependent meteorological variables (wind speed, wind direction, and stability class) into predetermined categories. Usually wind speed and stability class are subdivided into six categories each, and wind direction is subdivided into the 16 major compass points (N, NNE, NE, etc.), yielding $6 \times 6 \times 16 = 576$ combinations. Pollutant concentration at each receptor is then calculated for each of the 576 possible combinations. Next, the frequency with which each combination occurs is determined from meteorological data, and a joint frequency distribution (commonly called a STAR array) is derived. The STAR array is multiplied by the 576 concentrations to yield long-term average concentrations. Of these two methods, the hour-by-hour approach is attractive because in the process of calculating annual average concentration, it can also calculate 3- and 24-hr concentrations for comparison with air quality standards. The STAR data method is attractive because it uses far less computer time than the hour-by-hour approach.

Data Input: Two kinds of input data are required to run a dispersion model: pollutant source data and meteorological data. Source data include the pollutant emission rate of each source at the surface mine, often expressed in grams per second, and the location and extent of the source, usually expressed in a coordinate system consistent with the model. For point sources such as stacks, the gas exit temperature, exit velocity, stack diameter, and stack height are needed so that the model can compute the height of the plume above ground level. For line and area sources the plume rise is

more difficult to simulate. The source data needed in an air quality dispersion model are derived largely from an emissions inventory.

The meteorological data needed for dispersion models differs depending upon whether the model is a sequential hour-by-hour type or a long-term STAR type. The sequential models require wind speed, wind direction, and stability class for each hour modeled. The STAR data models simply require a matrix of joint frequency distributions. In addition, both model types often require inversion height (or *mixing depth*) and ambient temperature from which point source plume rise is computed. The meteorological data are either derived from on-site measurements collected at the surface mine over a period of time, or are obtained from measurements taken at nearby weather stations or airports. The National Climatic Data Center (NCDC), a facility within the National Oceanic and Atmospheric Administration of the US Department of Commerce, can provide meteorological data over most of the United States at a modest cost. Because many air quality regulatory agencies have specific policies regarding the use of meteorological data in models, it is wise to consult with the appropriate agency if the model predictions are to be used in support of a permit application.

Deposition: Particulate matter emitted from surface mines is removed from the atmosphere by gravitational settling and deposition. These phenomena tend to reduce ambient air particulate concentrations below those which would be experienced in the absence of deposition and settling. The magnitude of the reduction depends upon the size of the particulate matter and the distance at which the concentrations are measured, but it is possible that 60% of the airborne TSP mass at a surface mine may be removed from the atmosphere by deposition and settling (Wurmbrand, 1981). If an air quality dispersion model that does not account for these phenomena is used to simulate TSP concentrations, then it should be recognized that the predicted concentrations may be unrealistically high. At the present time there are no EPA-approved models that do a good job of simulating deposition and settling.

Selection of Air Quality Models

There are many Gaussian air quality models in use, but only a handful include features that make them desirable for modeling pollutant dispersion from surface mines. Three of the most widely used of these are discussed:

CDM: The Climatological Dispersion model (CDM) is a STAR data-type model that predicts annual average or seasonal concentrations (Busse and Zimmerman, 1973). CDM admits point sources and area sources only; line sources such as haul roads must be simulated by a series of adjacent point sources. A rural version of CDM, called CDMW, is used in many western states (Dailey, 1979).

ISC: The Industrial Source Complex (ISC) model (Bowers, Bjorklund, Cheney, 1979) is comprised of a short-term and a long-term version. The short-term version is an hour-by-hour model, while the long-term version uses STAR data input. Both versions admit point and line source configurations, as well as a variation of an area source termed a volume source. The ISC model attempts to account for many meteorological phenomena that many models ignore, among them stack downwash, rural or urban dispersion coefficients, limited complex terrain adjustment, and particle settling (but not deposition). The inclusion of particle settling capability coupled with very flexible source idealization has made this a popular surface mining model. However, these features come at the expense of greater computer execution time than

the other Gaussian models and are still not as good as they should be.

VALLEY: The VALLEY model (Burt, 1977) is a STAR data-type model that simulates annual average concentrations or, by creating an abbreviated STAR data input, can predict 24-hr concentrations. VALLEY is one of a few models that accepts receptor heights situated above the pollutant source, and for this reason it is often used to estimate pollutant concentrations in mountainous terrain. The method of handling high terrain causes the model to be notorious for predicting very high concentrations on elevated terrain when used in a *worst case* mode. VALLEY is a screening model that admits point and area source configurations, but does not account for particle settling or deposition.

EXAMPLE APPLICATION

In this section the individual steps leading to the acquisition of an air quality permit for a hypothetical surface coal mine are discussed. This example illustrates how air pollution regulations, ambient air monitoring efforts, emission inventories, and pollution modeling tie together.

The proposed mine in this hypothetical example is to be an open pit, truck and shovel operation with a life of 27 years. Maximum production of 14.5 Mt (15 million st) per year will be reached during the last 14 years of mine life. Run-of-mine coal will be transported from the pit by haul trucks to a two-stage crushing complex, and from there by conveyor to a storage silo. Coal will be shipped by rail to markets.

The only air quality permit needed to begin construction was that administered by the state air pollution regulatory agency. The state air pollution regulations embodied most of EPA PSD requirements and enforced ambient standards through a permitting process. New pollutant sources were required to secure state air quality permits, granted only after the applicant demonstrated that the proposed source would meet state ambient air quality standards, would apply BACT, and would meet applicable emission limitations. Additionally, new sources were required to submit one year of pre-construction monitoring data to the state agency to ensure that the sum of existing pollutant concentrations and anticipated future concentrations caused by the mine would not violate standards.

Because the requirement for one year of monitoring data was identified as the most time-consuming step in the permitting process, the mining company immediately set up the necessary monitoring equipment. Three PM-10 samplers (two collocated) were situated at two sites located along the prevailing wind direction on opposite boundaries of the proposed mine site. A 10-m (32.8-ft) tall meteorological tower was erected and instrumented to measure wind speed, wind direction, temperature, and wind direction fluctuation data.

An air pollution consulting firm was hired to design and operate the sampling system and reduce the data into quarterly reports for submission to the state regulatory agency.

Development of a comprehensive mining plan was begun shortly after initiation of the ambient monitoring effort. The mining company's engineers, working in conjunction with the company's environmental staff, specified coal handling equipment and pollutant emission control devices for competitive bid by vendors. The particulate matter control equipment was selected with two goals in mind: total point source emissions were to be kept below 227 t/y (250 stpy) so that the mine would not be subject to PSD regulations and equipment had to qualify as BACT. Performance guarantees from equipment vendors and a review of previous decisions by the regulatory agency as to what devices qualified as BACT ensured that these two goals were met. The truck dump, where bottom dump haul trucks unload into receiving hoppers, will be controlled by water sprays, and by negative pressure dust pickups vented to a baghouse. Similarly, the primary and secondary crushers will be vented to fabric filter baghouses. Above ground conveyors will be covered on the sides and top and vented to a baghouse. Prior to loading into railcars, coal will be stored in silos.

The mining company also made stringent commitments for the control of fugitive dust emissions. Prompt revegetation, minimization of disturbed area, and wind breaks were proposed as a means of controlling windblown dust. Dust from drilling is to be controlled by cyclone separators and shrouds and blasting is to be curtailed during high winds. The mining company planned to control dust from haul roads by use of chemical dust suppressants, by limiting haul truck speed to 64 km/h (40 mph), and by maintaining roads with a grader.

As soon as the mining plan was finished, and the dust control equipment and fugitive dust abatement practices were chosen, a complete emissions inventory was developed. The state regulatory agency asked that the mining company determine pollutant emissions and perform pollution modeling simulations only for the *worst-case* year—the year during which maximum particulate concentrations could be expected to occur off mine property. Initial calculations showed that the worst case year would be 2001, when TSP emission rates would be greatest because of long haul road lengths and high production levels. Equally important, that year is one in which the mine pit would be close to the plant boundary so that activities in the pit might induce high concentrations to which the public could be exposed.

Using the factors appearing in Tables 8 to 13 and other factors, an emissions inventory for the year 2001 was prepared. The point source emissions were computed to be well below the 227-t/y (250-stpy) limit, as illustrated in Table 14, and as a consequence the mine is clearly exempt from

Table 14. Particulate Nonfugitive Emission Rates from Mine Point Sources

Source	Emission Rate, st per year
Truck dump	19.2
Primary crusher	1.6
Secondary crusher	4.8
Transfers and conveyors	16.0
Silo load-in/load-out	0.1
Total	41.7

Metric equivalent: st × 0.907 184 7 = t.

Table 15. TSP Fugitive Dust Emission Rates

Source of Activity	Emission Rate, st per year
Topsoil removal and scraper travel	55.1
Overburden drilling	1.7
Overburden blasting	0.5
Overburden removal and replacement	181.5
Coal drilling	0.6
Coal blasting	0.8
Coal removal	144.6
Road construction and maintenance	168.0
Haul roads	566.3
Wind erosion	70.7
Total	1,189.8

Metric equivalent: st \times 0.907 184 7 = t.

PSD regulations. The fugitive TSP emissions summarized in Table 15 were expected to be considerably larger than the point source emissions. The haul road emissions account for nearly one-half of TSP emissions at the mine.

The next step in the preparation of the permit application was to model the air quality impact of the proposed mine. The particulate matter emission rates were divided into point, area, and volume source configurations and the location of each was identified on a map of the mining area. The source emission rate and location information were coded into a format for use in the ISC dispersion model. Similarly, the meteorological data collected during the year-long field data gathering effort were coded for use with the computer models. The models were then run, and the annual average and 24-hr TSP concentrations predicted to occur at model receptors outside the mine property were tabulated.

Because specific emission factors for PM-10 were not available, the state agency asked that modeled TSP contributions be multiplied by a constant factor of 0.27 to estimate PM-10 concentration contributions. The multiplicative factor was based on previous studies that suggest that 27% of total suspended particulate matter in the vicinity of surface coal mines is less than 10 μm in size (Anon., 1982).

The peak annual average PM-10 contribution from the mine was found to be 13 $\mu\text{g}/\text{m}^3$, which when added to the measured background concentration of 11 $\mu\text{g}/\text{m}^3$, was in compliance with the 50 $\mu\text{g}/\text{m}^3$ ambient air standard. The peak 24-hr modeled concentration of 48 $\mu\text{g}/\text{m}^3$, when coupled with the highest measured daily PM-10 background of 16 $\mu\text{g}/\text{m}^3$, was similarly lower than the federal 24-hr secondary standard of 150 $\mu\text{g}/\text{m}^3$. Hence, the modeling study indicated that the proposed mine would meet applicable PM-10 standards. The emission rates of other pollutants— SO_2 , CO, NO_x , and hydrocarbons—were so small that the state air pollution regulatory agency concluded that no modeling would be needed to show compliance with ambient standards for these pollutants.

With the emissions inventory and modeling effort completed, the permit application was nearly finished. Maps and drawings of the proposed mine, required by the state agency, were added, as were descriptions of pollution control equipment and anticipated annual coal production rates. Additionally, computations comparing expected emission rates with state emission limitations (New Source Performance Standard for coal preparation plants and process weight rate restrictions) were provided. The permit application was submitted to the state agency 15 months after the year-long field monitoring study was begun.

The state agency, following a statutory time frame for reviewing air quality permit applications, deemed the application complete 60 days after receipt and issued a preliminary determination of *conditional* approvability 90 days after judging the application complete. The preliminary approval was granted on the condition that the mining company agrees to continue monitoring particulate matter concentrations after mining begins.

6.8 Open Pit Rock Mechanics

RICHARD D. CALL
JAMES P. SAVELY

INTRODUCTION

Historically, the application of rock mechanics to surface mining has primarily been the analysis of the stability of slopes and was considered more theoretical than applied. In the first edition of *Surface Mining* (Pfleider, 1968), slope stability was included in the section on research and development. In the intervening years, slope design has become an integral part of mine planning rather than a research curiosity. This has come about with the development of improved data collection techniques (Call, et al., 1976), computer-aided stability analysis (Ross-Brown, 1979), and a reliability cost-benefit interfacing with mine planning (Kim, 1977). Since 1968, two comprehensive reference works on slope design have been published (Hoek and Bray, 1981; CANMET, 1976).

In addition to slope design, there are a number of other applications of rock mechanics to surface mining that utilize a common database. Table 1 lists the applications and the database. For purposes of this section, soil mechanics and rock mechanics are not differentiated. The underlying mechanics of stress strain and strength are the same, regardless of the classification of the material, as are the basic principles of determining the physical properties of a material and analyzing its response to imposed stress. Therefore, when reference is made to *rock*, it may be geologically a soil.

It has been the experience of the authors, both as mine staff geotechnical engineers and as consultants, that ground control difficulties more often have been the result of inadequacy in organization and implementation of a rock mechanics program than the lack of, or failure of, the technology to solve the problem. Therefore, in this section, the

authors have placed the emphasis on what to do, when to do it, and how to integrate rock mechanics with other aspects of mining rather than on the theoretical aspects of mathematical analysis.

An effective rock mechanics program requires careful organization and planning. Data collection must precede analysis so that problems are anticipated; otherwise, there may be insufficient time to collect data and important information may be lost. For example, displacement and water level time trends cannot be measured retroactively, bench faces may become covered or inaccessible, and drill core ground up for assay. On the other hand, there is never the time, manpower, or budget to measure everything; so the analytical approach must be kept in mind during data collection to ensure the appropriate information is collected with the resources available.

Interpretation and analysis should be kept current with data collection; otherwise, data collection can become an end in itself. File cabinets full of raw data may give the appearance of productivity but do not, in and of themselves, result in an optimum mine plan.

In the subsequent section, the emphasis is on data collection first to provide the background for analysis and designs. Geologic data collection and presentation are discussed in more detail than other aspects of rock mechanics because of their importance and the number of times we have found the geologic database inadequate.

Design Approach

Mine design and operational decisions are primarily cost-benefit optimizations. The objective is to extract the mineral

Table 1. Rock Mechanics Applications and Data Requirements for Surface Mining

Application	Data											
	Geology			Material Properties		Site Conditions			Operational Factors			
	Structural Domains	Major Structure	Fabric	Substance	Fracture	Hydrology	Stress Field	Seismicity	Mining Plans	Equipment	Production Rates and Costs	Current Slope Geometry and Displacement

Leaching	1	2	1	2	2	1			2			

reserve at the lowest cost, or to accept or reject a mining option on the basis of benefits being greater or less than the cost. In this context, the role of rock mechanics is to predict the behavior of the rock in response to mining in a manner that costs and benefits can be assigned.

The prediction of rock behavior is by no means straightforward. To make a rational analysis, a conceptual model must be developed that is mathematically tractable and cost effective. The complexity of natural materials and processes precludes an exact modeling; thus, an analysis is only an approximation of the real world.

Even with the simplification of modeling, the present analytical capability exceeds the ability to obtain the prerequisite input data on material properties, geology, and site conditions for the following reasons:

- 1) Material properties vary from point to point and access is limited, so obtaining representative samples is difficult.
- 2) There are uncertainties in field measurements and testing.
- 3) The magnitude and time of occurrence of the phenomena that affect rock behavior, such as rainstorms or earthquakes, are governed by such a complex interrelationship of factors that it approaches a chance event.

This uncertainty in the input data and analysis precludes an exact prediction of rock behavior. For this reason, the probabilistic approach has gained widespread acceptance in open pit rock mechanics. By appropriate sampling and testing strategies, the distribution of rock properties can be quantitatively estimated. These distributions can be used in explicit mathematical models or in Monte Carlo simulations so that the results of an analysis can be computed as a probability distribution rather than a deterministic single value based on an average or assumed single input value. For example, the stability of a slope can be expressed as the probability of failure, which is more useful for an economic risk analysis than a safety factor.

GEOLOGY

Applied geology emphasizes an overall view of general geology of the mine, which includes the distribution of rock units and the spatial relationships of major structures. For specific rock mechanics studies, additional information on major structure and rock fabric is needed. Rock fabric is the orientations and characteristics of minor structure, such as joint sets and foliation.

Major structures are treated as individuals in slope design because their location and extent are known. Bench face mapping and geologic interpretation are used to define major structure. Rock fabric, however, is treated statistically in design because a single orientation measurement and property determination on a joint may or may not represent those of the joint set. The statistics of populations where orientations and characteristics are described, not by a single value but by a distribution of values, are needed because of the recognized variability in joint properties within the joint set. Cell mapping, set mapping, and detail line mapping are used to obtain data for statistical analyses.

Bench Face Mapping

The bench face mapping technique is described by Peters (1978). This is the basic method for pit mapping whereby major structures, such as faults and contacts (traceable for at least two benches), are described by the points where they intersect the toe and crest of the bench. True strike directions are seen only where structures cross bench levels. A map showing several bench levels should be carried in the mapping

to tie geology through to successive benches (Fig. 1). In addition to plotting the major structure, comments should also be made on rock type, alteration, mineralization, rock hardness, and fracture frequency.

An appropriate mapping scale is the key to successful pit mapping. Mapping should provide sufficient information for interpretation, and it must be provided in time to be useful. Thus, a mapping scale should be selected that will allow mapping to keep pace with the mining. Extensive detail in one small area is less important than providing general geologic knowledge for the entire mine. Ideally, mapping is kept current within 100 m (400 ft) of the mining advance. The following guidelines can be used for selecting an appropriate mapping scale:

Pit Diameter	Mapping Scale
< 500 m (< 1500 ft)	1:400 (1:600)
500-1500m (1500-5000 ft)	1:1000 (1:1200)
> 1500 m (> 5000 ft)	1:2000 (1:2400)

Data from field sheets should be posted onto mylars the same day the mapping is done. These mylars should contain only factual information, not interpretation.

Geology Interpretation and Presentation

Interpretations of geology should be made on section mylar or sepia copies from the factual mylars. Keeping factual information separate from the interpretations makes reinterpretation at a later date possible with a minimum of effort.

The overall geologic picture is provided by a complete set of interpretive geology level maps and cross sections at a scale that shows the complete view of the mine plan. Generally, these maps are at the same scale as that used for mine planning. If geologic information is merely collected and not interpreted, the geology will not be used effectively in ore reserve estimation, ore control, mine planning, or slope design. Mine geologists must extend interpretations, based on intuition if necessary, for a distance of one and a half pit depths beyond the final pit limit. Otherwise, mine planners and engineers must make the necessary geologic assumptions usually based on less knowledge than the geologists have. One assumption that can be made in error is that no useful geologic information is available.

From the basic level maps and cross sections, geology is easily transferred to plans and the current pit composite. Geology maps are made for every planned mining level. Cross sections are made to show views of geology in the vertical plane on intervals determined by the ability to project geologic information. Overlays are generally made on selected maps to show alteration, mineralization, grade, or other features of interest.

Level maps and cross sections contain the following basic information: (1) pre-mine topography, (2) current topography, (3) original surface geology, (4) drill holes that show geology and grade, (5) old underground workings, and (6) mining push backs and final pit limit. The process of developing geology plan maps is illustrated in Fig. 2. Cross-section maps are developed in a similar manner.

Rock Fabric Data Collection

To develop an understanding of minor geologic features, such as joint sets or foliation, mapping must provide a systematic and consistent measurement. This implies the use of coding forms suitable for data entry and compatible with computer processing (Fig. 3). Coding provides the desirable aspect of a checklist to ensure that all needed information

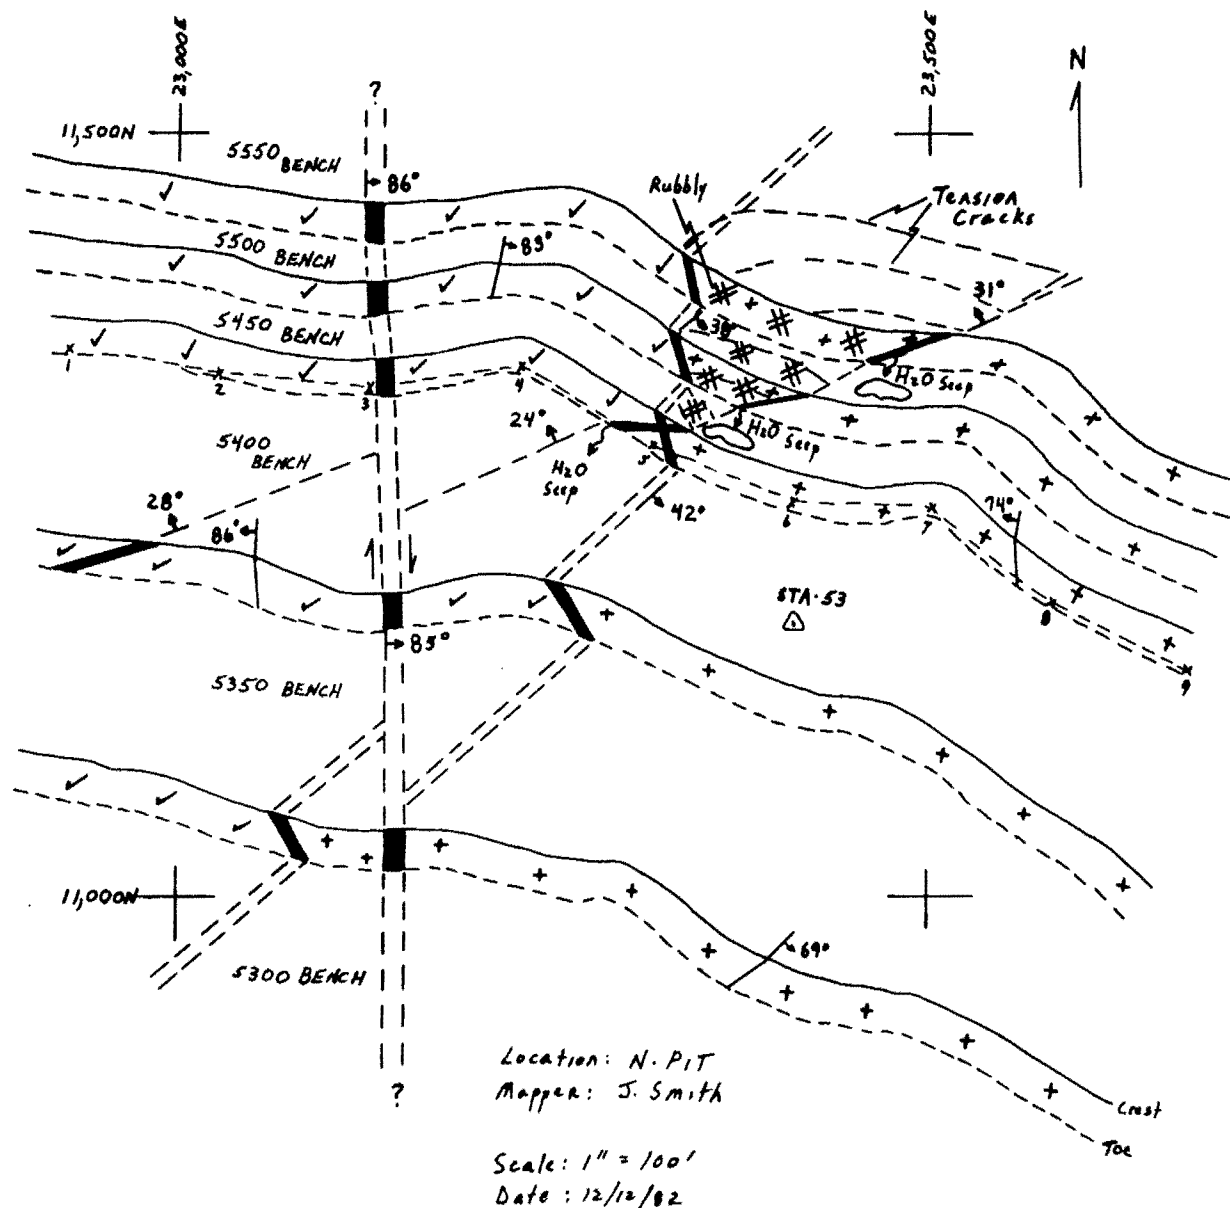

Fig. 1. Bench face mapping field sheet.

is recorded. Minor geologic features are analyzed statistically, which requires that an unbiased sample of the true distribution of values be obtained. All numbers should be recorded exactly, and not rounded, to provide continuous rather than discrete information.

There are three methods for obtaining rock fabric data: (1) cell mapping (Call, et al., 1976); (2) set mapping (Call, et al., 1976); and (3) detail line mapping (Piteau, 1970; Call, et al., 1976). Each method has a specific purpose, and each has advantages and disadvantages.

Cell Mapping: This method is used when there are large, extensive exposures of rock, such as along benches in an open pit or on large natural outcrops. Consecutive mapping cells are established along the strike of the exposure. Orientations are characteristics of the most significant structures are recorded. This mapping provides a continuous measurement

that gives an estimate of the recurrence of structure orientations and, thus, a probability of occurrence. Experience has shown 30 to 40 cells are needed in each structural domain to describe the statistical distributions needed in slope design.

Cell mapping is subjective because it relies on the observer's judgment as to which fracture sets are significant; therefore, an observer bias is built into the data. The advantages to this method are that fracture characteristics and their frequency of occurrence can be determined over large areas in relatively short time.

Set Mapping: This method is used in place of cell mapping when rock exposures are not suitable for establishing consecutive cells, or for reconnaissance-type mapping. It provides information on fracture orientations and characteristics, but not quantitative information on recurrence over a large area. It is a fast mapping method, but like cell mapping,

the observer makes a judgment as to the significance of each fracture set, thus introducing an observer bias to the data.

Detail Line Mapping: This method has the least observer bias of the three methods for obtaining statistical information on the fracturing, but it also provides the least area coverage. Generally, this method is used to determine rock fabric when there is no previous knowledge of the fracture patterns or distribution forms of the fracture characteristics. This method is a spot sampling technique where sampling sites are chosen along the bench face or other available rock exposure.

At each mapping site, a measuring tape, which serves as a reference line, is stretched along the rock exposure. The orientation and characteristics of every fracture or its projection, which intersects the line, are recorded. Usually, an arbitrary length cutoff of about 0.3 m (1 ft) is used and fractures with lengths less than the cutoff are not recorded.

Major disadvantages to this method are that it is tedious and time-consuming, and only a small area is covered. Unless supplemental cell mapping or set mapping is done, significant fracture sets can be completely missed.

Rock Fabric Data Processing

Data from the coding forms are entered into the computer from which Schmidt plots (lower hemisphere, equal area projections) are produced (Billings, 1954; Hoek and Bray, 1970). These plots are used in determining structural domains and potential failure modes (Fig. 4).

Conventional methods for developing histograms and determining distribution forms are used to describe the fracture orientations and characteristics in preparation for stability analysis and slope design.

Structural Domains

A structural domain is an area usually bounded by a major structure, such as faults or contacts, where orientation patterns of the fractures and their characteristics can be considered similar. An example of structural domain definition is given in Fig. 4, and more discussions can be found in Chap. 2 of the *CANMET Pit Slope Manual* (1976).

Oriented Core

Oriented core is often used to supplement surface mapping data and to collect samples of natural fractures in areas behind proposed pit walls and at depth. Orientation of the entire core from the drill hole is not necessary for fracture studies. All that is needed is a statistical sampling of the fracture attitudes. For this reason, some of the simpler and less expensive core orientation methods, such as the clay imprinter are recommended (Call, et al., 1982). More sophisticated methods of core orientation are available from Christensen in Salt Lake City.

ROCK MECHANICS PROPERTIES AND ROCK MASS STRENGTH

It is important to differentiate between the rock substance which is intact rock, and the rock mass, which includes both intact rock and rock fabric.

Strength refers to the "maximum stress that a body can withstand without failing by rupture or continuous deformation." Application in analysis and design determines the loading conditions which define the strength value of interest.

In open pit slope design, compressive strength of the substance is important as a classification criteria. Also, block flow stability analysis, where crushing of the rock is consid-

ered, uses the mean and standard deviation of compressive strength as input parameters (Coates, 1981).

In crushing, drill performance, and excavation studies, compressive strength becomes important because of the relationships that might be developed between strength and energy requirements, abrasiveness, drilling rate, and digging or ripping characteristics.

When potential failure planes are not continuous, intact rock bridges must be broken for failure to occur and the rock substance tensile and shear strength are required.

In rock mechanics the strength of the rock mass will determine its behavior under stress. However, rock mass strength cannot be obtained by laboratory testing or direct measurement; it must be inferred from the measurable com-

ponents of the rock mass: rock substance strength, fracture strength, rock fabric, major structure, and block size. Determining rock fabric and major structure characteristics were discussed previously. The other parameters can be determined from laboratory tests, field methods, and estimation methods (Table 2).

Laboratory Tests

Uniaxial and triaxial compression tests are conducted in the laboratory on cylindrical samples, usually of drill core, to provide rock substance strength. Deformational properties, Poisson's ratio, and modulus of deformation are also determined from the uniaxial test.

Poisson's Ratio (μ) is the ratio of lateral strain (ϵ_{lat}) to longitudinal strain (ϵ_{long}) under normal uniaxial stress (σ_n) and is a measure of the directional variability in the deformability of the rock substance.

Modulus of Deformation (E) is a measure of the stiffness of the rock substance under normal uniaxial stress. It is the ratio of uniaxial stress to longitudinal strain.

Tensile Strength

Of the two most common tests for determining tensile strength, indirect tension (Brazilian) and direct tension, the Brazilian test is the least expensive, easiest, and most commonly used.

A Brazilian test consists of diametrically loading a disk of rock core until it fails. Theoretically, the diametrical loading induces a tensile stress in the center of the disk, and failure occurs parallel to the direction of loading.

The direct tension test pulls a cylindrical rock sample at both ends until the specimen fails.

Direct Shear

The direct shear test consists of taking two blocks of rock that are separated by a natural fracture, applying a load perpendicular to the fracture, then measuring the shear load required to displace the blocks relative to each other. Samples of fault gouge or low strength rock, where shear failure of the rock substance is expected, are tested in a similar manner by shearing through a single block or core of the intact

Fig. 4. Structural domains and rock fabric plots.

Table 2. Methods of Determining Characteristics of the Components of the Rock Mass

Rock Mass Component	Laboratory Test	Field Method	Estimation Method
Substance compressive strength	Uniaxial, Triaxial	point load test, Schmidt rebound hammer	manual index tests
Substance tensile strength	Indirect (Brazilian), Direct	none	tensile strength = uniaxial compressive strength \div 10
Substance shear strength	Direct	in-situ direct, vane	shear strength = uniaxial compressive strength \div 2
Fracture shear strength	Direct	in-situ direct, tilt	Barton's classification, back analysis of failure, geometries
Rock fabric	N/A	mapping	none
Major structure	N/A	mapping	none
Block size	N/A	RQD, core logging, screen tests, inspection of muck piles and dumps, volumetric joint count, block size index, photoanalysis	simulation of fracture geometry

material. Although the shear strength of intact rock can be obtained from triaxial tests, the direct shear test is preferred by the authors since it more closely simulates the stress conditions used in slope stability analysis.

The resulting relationship between normal stress and shear stress can be analyzed statistically, and a mathematical linear or power *best* fit can be calculated:

$$\tau = C + \sigma_n \tan \phi \text{ (linear)}$$

$$\tau = k \sigma_n^m \text{ (power)}$$

where τ is the shear strength, C is cohesion, σ_n is the normal stress, ϕ is the friction angle, and k, m are power curve parameters relating shear strength and normal stress.

Commonly, the linear approximation is used because the values of friction angle and cohesion are easy to relate to field problems and it has been an accepted method for many years. However, the power fit is considered more representative of the shear strength along fracture surfaces. At low normal loads, common to slope stability problems, the upper fracture surface tends to ride up and over irregularities on the lower surface. As the normal load is increased, shearing of the irregularities occurs. The resulting power relationship shows a steep curve at low normals that tends to approach zero at zero normal load, instead of a mathematically determined cohesion intercept as in the linear model. The linear intercept leads to overestimation of the available shear strength at low normals. For a limited range of normals, the linear fit is a reasonable estimator of the shear strength. Because of the potential nonlinearity of the shear strength curve, it is important to conduct shear tests in the anticipated range of normals.

Table 3 lists some typical strength and deformation properties of rock substance for some common mine rocks. Table 4 lists some typical fracture strength properties. Values from these tables might be used for preliminary analysis until results are available from site-specific testing.

Field Methods

The Schmidt hammer is a tool originally developed for testing concrete. The hammer is essentially a spring-loaded piston. The cocked piston is placed against the rock to be tested and triggered. The height of the rebound of the piston is measured, which is a measure of the rock hardness. A correction is made to standardize results based on the orientation of the hammer during testing. Schmidt hardness is

related to the compressive strength of the rock substance (Brown, 1981). The test is unreliable and considerable variability in strength estimates occurs. Several measurements should be taken at each site.

Point load tests can be done on either rock core or irregularly shaped specimens. The test equipment is a portable machine similar to a core splitter, consisting of a loading apparatus and an additional system to measure load and distance between the loading plates. A point-load strength index is calculated from the failure load and the sample dimensions. Corrected results from this testing often correlate with uniaxial compressive strength of rock substance. It is a simple, reliable, and inexpensive means to measure substance strength and the results are useful for rock classification purposes. Procedures for conducting these tests have been developed by the International Society for Rock Mechanics (Brown, 1981).

In situ direct shear tests can be used to test shear strength of low strength soil-like rocks and fracture surfaces in hard rock. The advantage to this test is reportedly that in situ site conditions, which can influence shear strength, are included in the testing. However, the sample preparation at the site, in fact, changes the actual conditions. The main disadvantage is that the test is time-consuming and can be expensive. In the majority of cases, it is better to collect a number of samples and test them in the laboratory than to spend the same amount of money on one in situ test. The objective should be to describe the variability in rock mass strength and, although less precision may introduce some variability, it is better to have a statistical sampling instead of one precise point.

Vane shear tests can be conducted in soil-like materials, and there are ASTM standards for conducting these tests (Sowers and Sowers, 1970). The vanes are essentially two crossed blades on a rod. The vanes are forced into the soil-like substance and then rotated. The torque required to shear the soil-like substance is measured. Shear strength is correlated to the size of the vane and the torque.

Tilt tests to determine shear strengths of fractures or rock fill in the field have been suggested by Barton (1982). He proposes corrections to extrapolate the information for use in design. This test is simple and inexpensive and, in the case of fractures, simply involves a measure of the size of the blocks tested and measuring the tilt angle at which one block

of rock slides on another. For rock-fill materials, Barton proposes the construction of a tilt box to contain the rock fill, but the test procedure is the same as for fractures.

Rock Mass Characteristics

Block size is an important characteristic of the rock mass for crushing and grinding, leaching, excavation, drilling, and blasting, as well as the effect it has on rock mass strength.

Block size index is one measure of block size (Brown, 1981). To determine the index, a bench face is selected that appears consistent in fracturing and rock type. Typical maximum, minimum, and mode block sizes are measured, and the number of different fracture sets bounding the measured block are noted. Information on the number of fracture sets

forming the block is used to adjust block volume calculations. Size distribution curves might be estimated from this data for each structural domain.

The volumetric joint count is the sum of the number of joints per meter for each joint set. A bench face is selected as in the block size index determination. For each joint set, average true spacings of the joints in each set are calculated from the number of joints in the set occurring over a specified distance measured normal to the joint set. The volumetric joint count is the sum of the number of joints per unit length for all sets. The following is an example.

Set 1: 6 joints in 20 m (65.6 ft)

Set 2: 2 joints in 10 m (32.8 ft)

Set 4: 20 joints in 5 m (16.4 ft)

$$\begin{aligned} \text{Vol. } ___ \text{ Count} &= 6/20 + 2/10 + 20/10 + 20/5 \\ &= 0.30 + 0.20 + 2.00 + 4.00 \\ &= 6.5 \text{ joints/m}^3 \end{aligned}$$

Block shape, number of joint sets, and joint lengths should be recorded to give a better description of the block size.

Screen tests could also be devised for size gradation determinations by constructing several size grizzlies and coarse screens. These are time-consuming tests and equipment construction can be expensive. Screening can be done only on blasted or loose rock and representative sampling is difficult.

Inspection of muck piles and dumps also gives an indication of block size and shape. The procedure is similar to the block size index where maximum, minimum, and mode block sizes are measured.

Usually, blasting tends to open up existing fractures and actual rock breakage is small. Therefore, the block sizes measured from blasted rock and dumps are often a reasonable estimate of in situ block size.

Rock quality designation (RQD) and core logging also provide information on the degree of fracturing, thus, the block size. In some instances, screening of the entire drill core will give a size distribution curve that is reasonably accurate for the lower range of block sizes. RQD, in the strictest sense, is a measure of all pieces of core greater than 10 cm (4.0 in.) in length expressed as a percentage of the total length in the drill run, and could be considered as a measure of +10 cm (+4.0 in.) rock blocks.

Estimation Methods

The Unified Soil Classification, which includes both quantitative and descriptive information, is a classic manual index test to determine characteristics of soils (Lambe and Whitman, 1969). Other soil indices can be found in Sowers and Sowers (1970). In geology and rock mechanics work, the rock hardness index proposed by Jennings and Robertson (1969) and Piteau (1970) are used (Table 5). Kirsten (1982) gives a field identification procedure for estimating compressive strength and vane shear strength.

Rule of thumb criteria for estimating strength has de-

veloped over the years. One is for tensile strength of rock. Tensile strength is one-tenth to one-twentieth the compressive strength. One-tenth is generally the closer estimate. A similar rule might be used for shear strength of intact rock substance. Maximum shear strength will not exceed half the uniaxial compressive strength.

Barton (1982) has proposed a classification scheme based on the roughness of joints and joint wall hardness. This classification is used to estimate peak shear strength. Caution in using this method is warranted because analysis of many slopes should not be done using peak shear strength values. Residual strengths may be a better estimate of actual conditions.

If slopes are available where failed geometries are present, back analysis can be done to determine strength values required for stability by assuming the failures are at limiting equilibrium. In many cases, these results are the "best estimates" for shear strength because they have the loading, geometry, and shear strength relationships of actual field conditions. However, one significant parameter that often cannot be reconstructed for the back analysis is the water condition at the time of failure. The water condition can be

very critical to the stability calculation, and the assumption used will affect the results of the back analysis.

It should be noted that stable slopes are also useful indicators of strength because they give a lower bound, just as failed slopes give the upper bound of shear strength. If enough slopes in both failed and unfailed conditions can be observed, the actual strength values can be bracketed, and the ability to accurately estimate shear strength improves. McMahon (1976) reports on his study and use of back analysis in slope design.

Simulation to predict block size is becoming more common. The usual procedure is to randomly sample joint orientations and spacings and to make some assumption regarding joint lengths to model the fracturing. Numerical methods are generally used to calculate the size and number of blocks. Conceivably, this modeling could be used to develop size distribution curves for the rock blocks. There are, however, still major difficulties to overcome regarding appropriate length values before this method can be applied by people other than specialists. Additional work is being done using key block theory to describe rock block shapes and volumes (Goodman and Shi, 1985).

Table 5. Rock Hardness Index

Grade	Description	Field identification	Approximate range of uniaxial compressive strength, MPa
S1	Very soft clay	Easily penetrated several inches by fist	<0.025
S2	Soft clay	Easily penetrated several inches by thumb	0.025–0.05
S3	Firm clay	Can be penetrated several inches by thumb with moderate effort	0.05–0.10
S4	Stiff clay	Readily indented by thumb but penetrated only with great effort	0.10–0.25
S5	Very stiff clay	Readily indented by thumbnail	0.25–0.50
S6	Hard clay	Indented with difficulty by thumbnail	> 0.50
R0	Extremely weak rock	Indented by thumbnail	0.25–1.0
R1	Very weak rock	Crumbles under firm blows with point of geological hammer, can be peeled by a pocket knife	1.0–5.0
R2	Weak rock	Can be peeled by a pocket knife with difficulty, shallow indentations made by firm blow with point of geological hammer	5.0–25
R3	Medium strong rock	Cannot be scraped or peeled with a pocket knife, specimen can be fractured with single firm blow of geological hammer	25–50
R4	Strong rock	Specimen requires more than one blow of geological hammer to fracture it	50–100
R5	Very strong rock	Specimen requires many blows of geological hammer to fracture it	100–250
R6	Extremely strong rock	Specimen can only be chipped with geological hammer	> 250

Table 6. Attributes Used in Some Developed Classification Schemes

Classification Methods	Rock Substance Strength	Drill Core Quality, RQD	Joint Spacing	Joint Orientation	Joint Strength	Rock Genesis	Ground-Water Conditions

Plate tests and radial jacking tests can be used to estimate the deformation characteristics of the rock mass.

ROCK MASS CLASSIFICATION

Rock mass classification schemes are generally not sufficient design criteria for slopes. Their applicability has more merit for excavating, crushing, and leaching. Franklin, et al. (1971) discussed classification schemes based on fracture spacing and compressive strength of the rock substance to describe the rock mass. They then related it to the excavation characteristics of digging, ripping, and blasting.

Kirsten (1982) adapts classification to excavation and calculates an excavability index which relates to the equipment needed. He has developed his classification for both soil-like and hard rock applications.

A useful classification scheme provides comparisons of rock mass properties within a mine as well as a comparison between different mines. The classification should indicate some behavioral characteristic in a quantifiable manner. Then the classification is used to predict rock mass behavior in an area where the classification system is identifiable, which allows better planning and design before mining begins.

Available Classification Schemes

Classification schemes have been developed for a variety of purposes. Some mines may be able to adopt one of these classifications or modify it slightly to fit their needs. Others would have to develop their own classification based on the attributes of interest. Table 6 presents a list of some of the

better known classifications and the attributes upon which they are based. Table 7 presents current classification schemes and their applications.

Developing a Specific Classification Scheme

Classification schemes are based on time, space, physical properties, and relationship between properties. An example of a time-related attribute would be the seasonal fluctuation in ground-water level or the time-dependent movement of a pit slope. Space-related attributes are most common and would include the variations in such attributes as rock hardness or fracture frequency over mine areas, which in themselves are examples of physical properties of the rock mass. Relationships between properties would be exemplified by RQD, a property of the rock mass that is dependent upon both rock hardness and fracture frequency (Deere, 1968). Coates (1981) gives further discussion on developing meaningful classifications.

The most effective method for developing a useful classification is to decide on the attributes of interest and to develop a set of overlay maps displaying the areal distribution. Varnes (1974) is an excellent reference on the method of attribute selection and map development.

SLOPE DESIGN

Slope design involves analysis of the three major components of a mine slope: bench configuration, interramp angle, and overall slope angle (Fig. 5). Bench configuration is

Fig. 5. Definition of bench face, interramp, and overall angles.

defined by bench height, width, and face angle; the interramp angle is defined by the bench configuration; and the overall slope angle is defined by interramp sections separated by haul roads or mining levels. If through-going structures do not produce the possibility of large-scale failure and joints lengths are short, all slope angles will depend on the bench configuration.

Fig. 6 is a flow chart of the slope design process from data collection to mine design. After data collection, the steps in the design process are:

- 1) Determine design sectors.
- 2) Conduct stability analysis to estimate probability of failure and expected failure tonnages for bench interramp and overall slopes.

3) Develop maximum interramp slopes based on catch bench criteria.

4) Determine optimum slopes with a cost benefit analysis.

Design Sectors

Design slope angles within an open pit are influenced by rock strength, geologic structure, hydrologic conditions, pit wall orientation, pit wall height, ore distribution, and operational conditions.

Since any or all of these parameters vary from place to place in an open pit, the pit must be divided into design sectors within which these parameters are similar or will have a similar impact on slope design. Structural domain

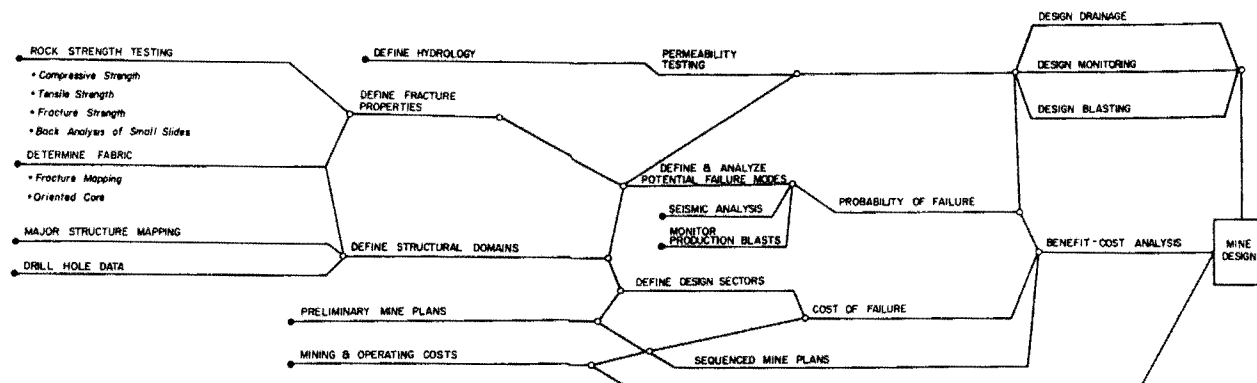

Fig. 6. Slope design flow chart.

boundaries are a primary criteria for sector limits. Changes in wall orientation are logical sector boundaries. Ore distribution and operational considerations affect economic considerations. For example, a concentrator on the edge of the pit would require a higher reliability for the slope for the same economic optimization than a similar pit wall without the concentrator.

Determining design sectors, and slope design in general, is necessarily an iterative process. The slope engineer needs the position, orientation, and height of the pit walls to design the slopes, but the mine planner needs the slope angles to design the pit geometry. Therefore, a pit plan has to be developed based on assumed slope angles. The design sectors are then selected and optimum slope angles are determined. Given these angles, the pit has to be redesigned and the slope angles reevaluated based on the new geometry. This is a formidable task using manual mine planning techniques. However, a new reserve pit can be developed in a few hours at a reasonable cost using floating cone or other pit design computer programs.

Stability Analysis

Stability analysis begins by selecting appropriate numerical models of potential failure modes for each design sector. These models are simplified geometric representations of the actual expected failure mechanisms. Typical failure models are shown in Fig. 7.

Plane Shear Failure: Plane shear failure occurs when the geologic structure has a strike parallel to or nearly parallel to the strike of the slope face and a dip flatter than the slope angle. Plane shear analysis determines the risk of sliding along structures of this type. Controlling factors in the analysis are (1) orientations of geologic structures, which determine whether the fractures have strikes (within about 20°) to the strike of the face and are daylighted (dip angles less than slope angle); (2) structure lengths, which determine

the probability of having a continuous through-going fracture; (3) structure spacing, which indicates the number of potential failure surfaces in the slope; and (4) structure shear strength, which determines the probability that, if a fracture satisfies all other criteria, the slope will displace along that fracture.

Step Path Failure: In step path failure, as in plane shear failure, it is assumed that sliding occurs along geologic structures subparallel to the slope. However, whereas plane shear displacement is assumed to occur along a single surface, the step path model assumes that failure is due to the combined mechanisms of sliding along surfaces dipping out of the slope (the master joint set) and either separation along geologic structures that are approximately perpendicular to the master set (the cross joint set) or tensile failure of the intact rock connecting members of the master set. Since the step path model does not depend on continuity of the master set, it often has wider applicability than does the plane shear model.

Simple Wedge Failure: Simple wedge geometry is the result of two planar, or nearly planar, geologic structures intersecting to form a completely detached prism of material. The weight of the material and acting hydrostatic forces drive the prism down the line of intersection. To be kinematically viable, the line of intersection must be daylighted. This implies that not only must the plunge of the intersection be less than the dip of the slope, it must also be directed toward a free face; i.e., the bearing of the intersection must be oriented within 90° of the dip direction of the slope.

Step Wedge Failure: Step wedge failure is similar to simple wedge, but in this case the structures that intersect to form the wedge do not need to be single, continuous features. Rather, as with step path, the combination of different structural sets forms the failure surfaces. A variation on this mode is a wedge formed on one side by a single planar surface and on the other by a step path geometry. There is a lack of sufficiently developed analysis for this failure mode, and simplifications are necessary if analysis is required.

Topping Failure: Some authors have proposed this failure mode as a primary failure mechanism (Goodman, 1980; Hoek and Bray, 1981; Brown, 1981). The topping failure mechanism relies on the development of thin slabs of rock that dip away from the slope face. In order to be a viable failure mode, the weight of the slabs must be directed outside their bases. Unless the slabs are very thin, sliding or crushing at the toe must occur before topping is initiated, and the analysis should concentrate on this toe area as the primary failure mechanism. Topping then would be a secondary failure mechanism that would have implications in progressive failure of a slope but would not be used as a primary analysis for slope design.

Rotational Shear Failure: Rotational shear failure occurs in slopes composed of material with low intact rock strength and sparse or nonexistent geologic structure, or material in which the geologic fabric is essentially randomly oriented. The failure surface, generally assumed to be circular or log spiral arc, represents the trajectory of the minimum ratio of shear strength to shear stress. The analysis determines the position of this critical failure surface, which is a function of slope geometry, material strengths, unit weights, and pore water pressure. Using a Monte Carlo simulation technique, material properties are varied for different conditions of slope geometry and pore water pressure distributions. The resulting distribution of the ratio of shear strength to shear stress provides an estimate of the probability of failure.

Fig. 7. Typical failure modes.

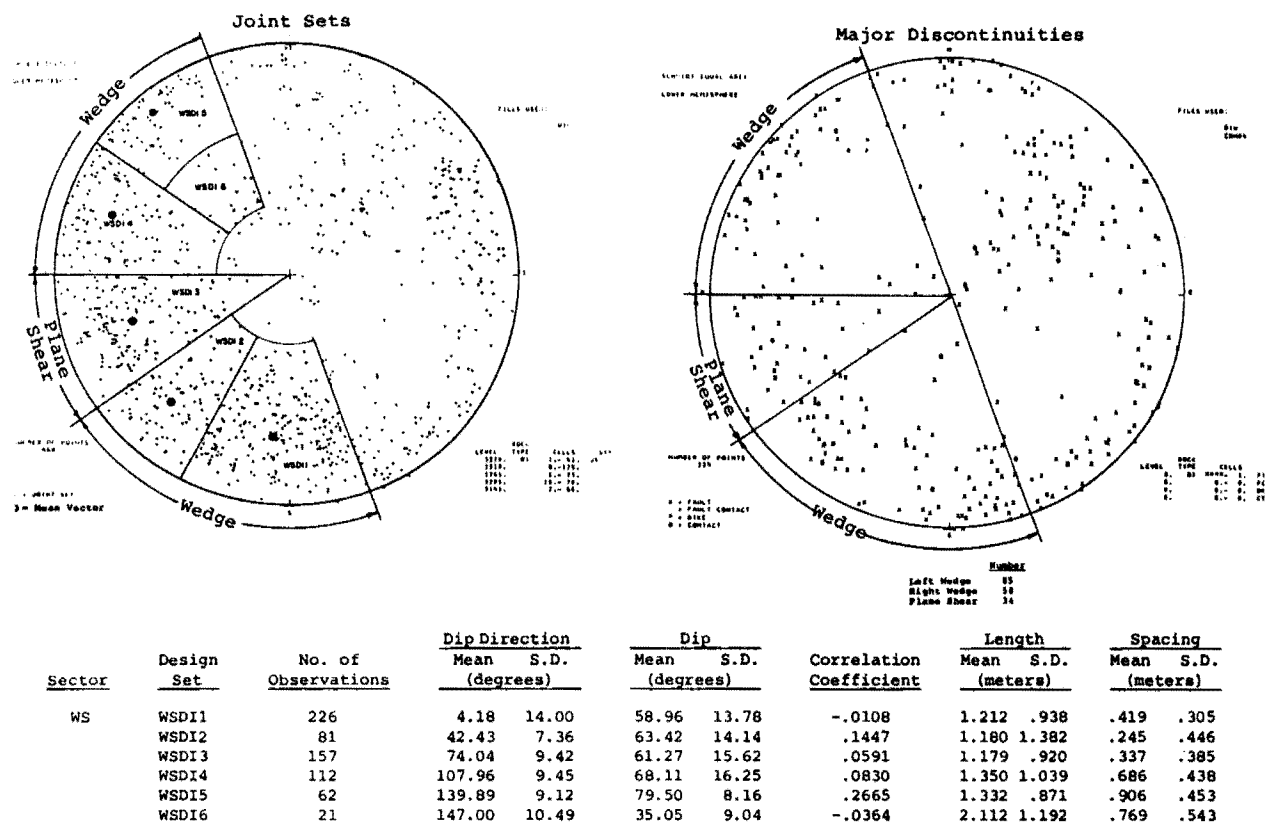

Fig. 8. Design set determination.

Block Flow

For deep pits or where the rock substance strength is low, the stresses in the wall, particularly in the toe area, can exceed the compressive strength of the rock substance. This can lead to crushing and progressive deterioration of the slope. Coates (1981) presents a simplified analysis to check for the potential of block flow. If the simplified analysis indicates that a potential, more detailed investigation is warranted, use a finite element analysis to estimate the stress distribution and a comprehensive triaxial strength testing program conducted to estimate the distribution of rock strength.

Determination of Potential Failure Geometry

By plotting the pit wall orientation of a design sector on Schmidt plots of the rock fabric and major structures, the impact for stability analysis can be developed (Fig. 8). The fractures and major structures are sorted by the failure-type orientations and the attitude, distribution length, and spacing distributions computed. These design sets may not correspond to geologic sets although the orientation boundaries can be adjusted somewhat to avoid splitting a geologic set. We have found that defining sets by visual or mathematical analysis, while appropriate for geologic fabric analysis, is less satisfactory for slope design, and it is best to use the wall orientation for determining design sets.

Probability of Instability

Determination of the probability of slope instability depends on the ability to quantify the variable character of the geologic parameters. Since physical geologic conditions, such

as discontinuity lengths, orientations, spacings, and shear strength vary within the rock mass, statistical distributions are used to represent these geologic parameters. Estimation of these statistical distributions generally requires a representative statistical sample, which often consists of many observations.

In the structurally controlled failure models, the probability of failure (P_f) for a single occurrence of a specified failure mode has three parts:

- 1) the probability that the dip exists (P_d);
- 2) the probability that the structure is long enough (P_l); and
- 3) the probability of sliding (P_s).

The probability of dip (P_d) and the probability of length (P_l) are calculated from the statistical distributions of the geologic structures.

The probability of sliding (P_s) is determined by calculating the probability that the shear stress exceeds the shear strength along the failure surface. This probability is calculated from the distribution of safety factors generated either by a technique called Monte Carlo simulation, which involves an iterative process of randomly sampling strength values from the shear strength distribution and subsequently calculating the safety factor, or by the application of closed form mathematical modeling.

Using the calculated mean and standard deviation of the distribution of safety factors and assuming a standard normal distribution, the probability of sliding, or the percentage of the total area of the distribution less than 1.0, can be calculated.

The probability of failure (P_f) for a single occurrence of

the particular failure mode is the probability that the mechanism is viable and that it will displace.

$$P_f = P_i * P_d * P_s$$

Since more than one potential occurrence of a specified failure mode can occur in a design section, the expected number of failures is the probability of failure times the probability of occurrence of the structures that constitute the failure geometry. Although the actual number of failures that will occur may be more or less than the expected number, it is the best estimate for design.

Utilizing the expected number of failures and the values calculated in the stability analysis, a probability of failures and expected failure volume curves can be developed (Fig. 9). The curves for all the potential failure modes can be composited to produce an expected failure volume curve for the design sector (see Fig. 10).

In the case of bench analysis, the distance the failure breaks back from the crest of the bench is composited rather than the failure volume.

Slope displacement will occur if the dynamic forces generated by earthquake-induced ground motion are large enough. The response of a slope to the external forces generated by an earthquake will depend mostly on the ground acceleration, the duration of the event, the rock mass strength, and the slope geometry. Slope movement, if it occurs during the seismic event, is assumed to cease when the event ceases. By calculating the total displacement that occurs during the event, a failure can be defined as that situation where displacement is great enough to disrupt normal mining operations (Glass, 1982). Probabilities of failure are generally increased, but often not significantly, when earthquake forces are included.

Bench Design

Bench faces are normally mined as steeply as possible; as a result, rock falls and raveling are inevitable. Thus, it is customary, and in many cases mandated by mining regulations, that catch benches are left in the pit wall to retain rock falls and raveling.

Analyses of rock fall mechanics by Ritchie (1963) demonstrated that falling rocks impact relatively close to the toe of the slope, but because of horizontal momentum and spin, can roll considerable distances from the toe. Based on his analysis, Ritchie developed width and depth criteria for a ditch at the toe of a slope to protect highways from rock fall. The concept was that the rock would impact in the ditch and the side of the ditch would stop the horizontal roll.

It is not practical to excavate a ditch in an open pit catch bench, but the same effect can be achieved by casting up a berm (Fig. 11). Assuming the berm can be emplaced with slopes of 1.25 to 1, the modification of Ritchie's criteria presented in Fig. 11 is recommended for open pit catch benches. For a given bench height and corresponding design bench width, the upper limit of the interramp slope angle becomes a function of the bench face angle.

The bench face angle, however, is not a unique value because the variability of the rock fabric produces varying amounts of backbreak. Backbreak is defined as the distance from the design bench crest to the actual bench crest. Fig. 12 is an example of the cumulative frequency distribution of measured bench face angles and theoretical bench face angles. The theoretical bench face angle is obtained from stability analyses assuming a vertical bench face and is the upper limit

Fig. 11. Design catch bench geometry. Minimum bench width = $4.5\text{m} + 0.2H$; berm height = $1\text{m} + 0.04H$.

Bench Height, m	Impact Zone, m	Berm Height, m	Berm Width, m	Bench Width, m
7.5	1.5	0.8	2	3.5
15	5	1	3	8
30	7	1	3	10

of possible bench face angles because it does not include the effect of blasting and digging. Comparison of measured and theoretical face angles at several properties gave a difference of 19° to 25° , except where the bench face was controlled by a strong geologic structure, such as bedding or foliation. In those cases, the measured and theoretical bench face angles were the same.

For an operating property, the measured bench face angles can be used for design. For a new property, the theoretical bench face angle adjusted for the effects of blasting must be used. Rather than choosing the mean bench face angle which would result in 50% of the catch benches less than the design width, or the minimum bench face angle which would result in unnecessarily flat slope angles, it is recommended that a desired catch bench reliability be chosen based on the potential for rock fall and the exposure of personnel. Catch benches in raveling ground being mined by front-end loaders should have a higher reliability than catch benches in massive ground mined with a large rope shovel. A bench face angle should then be chosen to give the desired reliability. For example, if a 90% reliability is desired, the bench face angle would be the angle where 90% of the bench faces will be steeper than the design angle shown in Fig. 12. Using the reliability criteria, the average bench width will be greater than the design width. In the sample shown in Table 8, a 52° interramp slope with a 90% reliability for a 10-m (32.8-ft) bench width has an average bench width of 15.4 m (50.5 ft).

Production bench heights are selected on the basis of equipment size and grade control requirements. There is considerable benefit in increasing the bench height on final

Fig. 12. Bench face angle distribution.

pit walls by leaving a catch bench every other mining level (double benching). A 5° to 8° increase in interramp slope may be achieved by double benching, assuming the same bench face angle. There is also the possibility of increasing the bench face angle with double benching because the majority of backbreak occurs as small failures of the crest. These small failures have less effect on the face angle of a high bench.

Controlled Blasting

The objective of production blasting is to produce the fragmentation required for excavation; however, the blast damage resulting from uncontrolled production blasting at the final wall reduces the bench face angles and, hence, the interramp slope angle. Therefore, controlled blasting in the vicinity of the final wall is desirable.

Measurement of blast damage indicates that a peak particle velocity of about 63.5 cm/s (25 ips) produces displacement on existing fractures and creation of new fractures. By monitoring blasts, the relationship between scaled distance and peak particle velocity can be established. Fig. 13 shows the results of such monitoring. Since the relationship is site-specific, it is preferable to monitor blasts at the property. The curves in Fig. 13 should be used only as a first estimate.

This scaled distance relationship can be transformed to a curve showing the maximum charge weight vs. distance from the face for 63.5 cm/s (25 ips) peak particle velocity at the face (Fig. 14). At distances where the maximum charge is greater than the charge per hole, blasting can be controlled by limiting the number of holes per delay. At closer ranges, the charge per hole must be reduced and the spacing adjusted on the holes picked.

The position of the blastholes relative to the catch benches should also be considered. By strategically placing the holes, damage to the catch benches can be reduced (Fig. 15). If blastholes are placed directly over the underlying bench crest, the subgrade damages the crest and reduces the bench width.

Table 8. Catch Bench Widths for Single and Double Benching in the Diorite East Structural Domain (Using Measured Bench Face Angles)

Fig. 13. Ground response to blasting (from Oriard, 1971).

Cost-Benefit Analysis

The simplest method for determining the optimum slope is to compute the incremental cost of slope failure and the incremental benefit per degree of slope increase (Fig. 16). If the incremental benefit is greater than the incremental cost, it is profitable to increase the slope angle. As the incremental cost exceeds the incremental benefit, it becomes unprofitable to increase the slope angle. In general, incremental benefit decreases while incremental cost increases with slope angle. The angle where the two curves cross is the economic optimum, as shown in the example in Fig. 16.

The cost of slope failure is determined by assigning cost models to expected failure volumes and possible mining responses. The benefit is the market value of the recoverable commodity minus the mining and processing costs. Kim (1977) discussed cost models and cost benefit analysis in more detail.

A more sophisticated analysis is to run a Monte Carlo simulation of the sequenced mine plans, applying the probability of failure schedule to include slope failure costs in the cash flow analysis. This way, the effect of interim slope failure and the time cost of money can be included. This type of analysis was developed for the CANMET *Pit Slope Manual* (Kim, 1977).

The cost-benefit approach, using probabilities of failure, provides a methodology by which the risks and costs of failure can be compared with the corresponding benefits for

Fig. 14. Controlled blasting criteria (diorite).

Fig. 15. Blasthole layout.

Fig. 16. Idealized incremental cost-benefit curves showing the economic optimum interramp angle.

any design. The benefit-cost approach does provide an optimized design unlike safety factor methods where the design is considered to be so conservative that little risk or cost of failure is expected. This apparent conservatism can be misleading, as evidenced by the failures of a large number of supposedly *safe* geological designs.

The fact that a slope is designed with some risk of failure must not be viewed as a disregard for safety concerns. Almost any economically viable option will have some probability of failure, and it is better to be aware of the level of that risk. Sufficient, suitable monitoring must be provided to detect instability at an early, noncritical stage to allow for remedial engineering and initiation of safety measures.

MONITORING

In any open pit mine, some slope instability can be expected. The instability can vary from bench sloughing to large-scale slope movement. Because of the inherent variability of rock strength and geologic structure, the uncertainties associated with sampling and measuring rock characteristics, and the mathematical and geometric approximations of the stability analysis, even a *safe* slope, designed to some customary safety factor, has a finite probability of instability.

Acknowledging that slope instability can occur leads to commitment to a monitoring program that ensures safe working conditions. The objectives of pit slope monitoring are (1) to maintain safe operational practices for the protection of personnel, equipment, and plant facilities; (2) to provide advance notice of instability, thus allowing for the modification of mine plans to minimize the impact of slope displacement; and (3) to provide geotechnical information to use for analyzing the slope failure mechanism, for designing appropriate remedial measures, and for conducting redesign of the slope.

Surface displacement measurement using conventional survey equipment and extensometers has been the most

widely used method for monitoring. It is still the most cost effective.

Survey Network

A survey network consists of targets on the pit slope and instrument stations from which angles and distances to the targets are measured. If a total station EDM instrument is used, approximately 3 min will be required for each reading; thus, about 30 to 40 prism targets can usually be surveyed in a half day. Using a distance meter EDM and a theodolite in combination takes about 5 min per reading.

The survey network has several primary functions.

- 1) It establishes a surveillance system to detect initial stages of slope instability.
- 2) It provides a detailed movement history in terms of displacement directions and rates in unstable areas.
- 3) It defines the extent of the failure area.

Tension Crack Mapping

One early, obvious indication of slope instability is the development of tension cracks. By systematic mapping of these cracks, the extent of the unstable area can be established. The ends of the cracks should be flagged so that on subsequent inspections new cracks or extensions of existing cracks can be identified.

Wire Extensometers

Portable wire extensometers can be used to monitor areas of active instability and to provide backup for the survey system. They should be positioned on stable ground behind the last visible tension crack and the wire should extend out to the unstable area. The length of the extensometer wire should be limited to approximately 60 m (197 ft) because sag can produce inaccurate readings. Usually 15 to 20 kg (33 to 44 lb) of counterweight is needed for such a length, depending on the weight of the wire.

Wire extensometers can be set up as a warning device by affixing a switch several centimeters (inches) above the counterweight. Significant displacement will trip the switch and activate a warning light or siren.

Other Surface Displacement Devices

Tiltmeters and manometers can be used to measure displacement across tension cracks when the displacement is predominantly vertical.

Subsurface Displacement Devices

Subsurface information on instability is needed when surface displacement cannot be used to infer the extent of the instability. Shear strips or a coaxial cable with a fault finder can be used to locate failure surfaces, but these systems are go/no-go devices. Borehole inclinometers measure angular deflection of the borehole and will give the deformation normal to the hole, thus locating failure surfaces. Borehole extensometers measure deformation parallel to the borehole. These extensometers are costly and difficult to use and are only suitable for special applications.

Piezometers measure ground-water levels and pore pressure. Measuring ground-water levels is an important part of monitoring and simple standpipe open piezometers are usually sufficient. However, if there are areas of low permeability or confined aquifers, or when rapid response to reduction in pore pressure needs to be monitored, pneumatic or electric devices may be required.

Microseismic monitoring has historically been expensive because of the electronic equipment needed. However, the lessening cost of equipment in recent years and its increased reliability are making this technique more attractive. Exper-

iments with microseismic recordings have established that there is a correlation between rock noises and slope movement.

Guidelines for Monitoring

- 1) Measure obvious things first. Surface displacement is the most direct and most critical aspect of slope instability.
- 2) Simpler is better. The reliability of a series system is the product of the reliability of the individual components. A complex electronic or mechanical device with a telemetered output to a computer has significantly less chance of being in operation when needed than do two stakes and a tape measure.
- 3) Precision costs money. The cost of a measuring device is often a power function of the level of precision. Measuring to ± 1 cm (0.39 in.) is inexpensive compared to measuring to ± 0.0001 cm (0.00039 in.). A micrometer is unnecessary for monitoring slope movement that has a velocity of 5 cm/d (2 ips).
- 4) Redundancy is required. No single device or single technique tells the complete story. Backup devices are needed.
- 5) Timely reporting is essential. Data collection and analysis must be rapid enough to provide information in time to make decisions. Reducing last week's data and telling the mine superintendent that the slope was moving Thursday when a shovel was buried Sunday does not lead to pay raises.

Data Reduction and Reporting

The following measurements or calculations should be made for each survey reading:

- 1) Date of reading, incremental days between readings, and total number of days the survey point has been established.
- 2) Coordinates and elevation.
- 3) Magnitude and direction of horizontal displacement.
- 4) Magnitude and plunge of vertical displacement.
- 5) Magnitude, bearing, and plunge of resultant displacement vector.
- 6) Rates of horizontal, vertical, and resultant displacements.

Both incremental and cumulative displacement values should be determined. Calculating the cumulative displacement from initial values rather than from summing incremental displacements minimizes the effects of occasional survey aberrations.

Slope displacements are best understood and analyzed when the data are graphically displayed. For engineering purposes, the most useful plots are:

- 1) Horizontal position (northing vs. easting).
- 2) Vertical position (elevation vs. change in horizontal position, plotted on a section in the mean direction of horizontal displacement).
- 3) Displacement vectors (plotted on a plan map).
- 4) Cumulative total displacement vs. time.
- 5) Incremental total displacement rate (velocity) vs. time.
- 6) Schmidt plots of total displacement vectors.

Daily precipitation and the number of tons mined beneath the slope should be added to the graphs as histograms to compare these records with slope movement.

A monthly slope stability report should be prepared for mine management. This report serves the dual purpose of providing information to decision makers and providing the discipline to document slope behavior. Direct, informal communication also should be maintained with pit operations on a daily basis in the case of mining in an active slide area.

REMEDIAL MEASURES

With an economically optimized slope design, some degree of slope instability can be expected. Minimization of the adverse effects of slope instability must be accomplished through judicious mine planning and establishment of operational contingencies.

There are several principles of slope mechanics that should be kept in mind in dealing with slope instability.

Slope failures do not occur spontaneously. A rock mass does not move unless there is a change in the forces acting on it. The common changes that lead to instability in an open pit are removal of support by mining, increased pore pressure, and earthquakes.

Most slope failures tend toward equilibrium. It is an observed phenomenon that as a slide displaces, the toe pushes out and the crest recedes. Such displacement reduces the driving force and increases the resistance force so that the displacement rate is reduced until movement stops. When high pore pressures are involved, a similar balance is attained. Displacement causes dilation of the rock mass. As a result, pore pressures drop and the effective shear strength increases. This mechanism explains the stick slip movement of some slides, in which recharge increases the pore pressure in tension cracks, resulting in renewed displacement. There are exceptions to this generalization, but they are usually the result of reduction of shear strength due to shearing of asperities or changes in the forces acting on the rock mass.

A slope failure does not occur without warning. Prior to major movement, measurable deformation and other observable phenomena, such as development of tension cracks, occur. These phenomena occur from hours to years before major displacement. However, single bench sloughing directly associated with mining does occur rapidly. While a slope failure does not occur rapidly without warning, deformation and tension cracks can occur without major displacement.

Detection of Instability

The first step in slope management is the identification of potential failure areas such as faults, breccia dikes, and/or jointing with attitudes that would form a failure geometry. Data for this identification would come from geologic pit mapping. Areas of higher water levels are also potentially unstable and should be identified.

The second step is monitoring areas that are potentially unstable and/or show evidence of instability by displacement and tension cracks.

On the basis of monitoring and mapping, the geometry of a failure can be determined and predictions made of future behavior.

Slide Management

When instability occurs there are a number of response options:

- 1) Leave the unstable area alone.
- 2) Continue mining without changing the mine plan.
- 3) Unload the slide through additional stripping.
- 4) Leave a step out.
- 5) Partial cleanup.
- 6) Mine out the failure.
- 7) Support the unstable ground with cable bolts.
- 8) Dewater the unstable area.

The choice of options or combination of options depends on the nature of the instability and the operational impact. Each case should be evaluated individually and cost-benefit

comparisons conducted. The following are guidelines on the choice of options.

1) When instability is in an abandoned or inactive area, it can be left alone.

2) If the displacement rate is low and predictable and the area must be mined, living with the displacement while continuing to mine may be the best action.

3) Even though unloading has been a common response, in general it has been unsuccessful. In fact, there are situations involving high water pressure where unloading actually decreases stability.

4) Step-outs have been used successfully in several mines. The choice between step-out and cleanup is determined by the tradeoff between the value of lost ore and the cost of cleanup.

5) Partial cleanup may be the best choice where a slide blocks a haul road or fails onto a working area. Only that material necessary to get back into operation need be cleaned up.

6) Where the failure is on a specific structure and there is competent rock behind the structure, mining out the failure may be the optimum choice.

7) Mechanical support may be the most cost-effective option when a crusher, conveyor, or haul road must be protected.

8) Where high water pressure exists, dewatering is an effective method of stabilization that may be used in conjunction with other options.

Contingency Planning

Mine planning should have the flexibility to respond to slope instability. Rather than an "after the fact" crisis response to forced deviation from a rigid mine plan, contin-

gency plans should be prepared in advance so that the response to slope instability is well thought out.

Operational flexibility should be built into the mining plan; for example:

1) Adequate ore should be exposed and accessible so that production is not dependent on a single location.

2) There should be more than one access road into the pit for service vehicles.

3) Whenever possible, double access to working benches should be maintained.

4) Production scheduling should have a provision for slide cleanup.

Excavation

Equipment selection and estimation of production rates and costs require a knowledge of the rock mass properties. A simple classification system based on rock substance compressive strength and fracture frequency can be used (Franklin, 1971) (Fig. 17). Kirsten (1982) has developed a classification that includes fracture and equipment characteristics.

Regardless of the classification system used, it is important to zone the excavation area rather than use average values. Although the average rock properties may indicate that blasting is not required, ignoring the 20% that does require blasting can have a devastating impact on mining costs.

CRUSHING AND GRINDING

Miners often attempt to improve fragmentation by altering blasting practices, but generally after experience and disappointment, will go to crushing because it is the only way to guarantee a uniform product size. In hard rock,

Fig. 17. Excavation classification (from Franklin, et al., 1971).

fragmentation can only be improved to a block size consistent with the fracture intensity. This is because the fractures are inherently weaker than the surrounding rock substance and the principles of fracture mechanics apply. These principles do not allow significant rock breakage, particularly with low velocity explosives such as ANFO, because less energy is required to open or extend existing fractures than to initiate new fracture and break rock substance. Some pulverization of the rock occurs immediately near the blasthole and, if costs allowed, high velocity explosives and a blasting pattern could be designed to pulverize the entire rock mass. Practically, however, the volume of pulverized rock in a blasthole is very small and probably insignificant when compared to the total volume of rock that is thrown into the muck pile.

Another consideration in attempting to improve fragmentation is that unless care is taken, mining costs could be significantly increased if the stability of final pit walls is decreased because of blast damage. To properly determine crushing requirements, the rock hardness, the size of the blocks to be crushed, and the tonnages needing crushing need to be known. These are parameters that will, in part, determine energy requirements, crusher size, grizzly size, abrasiveness, maintenance schedule, and equipment life. Siting of the crusher might be based on proximity to the material that requires the most crushing; thus, spatial distribution of large blocks must be known. Ultimately, conveyor belt size and other processing equipment will be selected based, in part, on the ability to crush materials to a specified size.

Rock Hardness

Compressive strength is the best indicator of rock hardness for crushing. Compressive strength can be estimated from laboratory tests on core from drill hole or rock blocks, from point load tests on irregular rock samples or drill core, or from a rock hardness classification. If rock hardness is plotted on level maps next to the drill hole locations or sample sites, the spatial distribution of hardness can be defined.

Block Size Prediction

Block size distribution can be determined by simulation and direct measurement. Both estimation methods require a knowledge of *fracture frequency*, i.e., a count of the number of fractures per meter (foot) without regard to orientation or the manner in which the fractures are separated. Rock Quality Designation, RQD, can also be used. A relationship between RQD and fracture frequency was reported by Priest and Hudson (1975). First it is necessary to define areas of similar fracture frequency on level maps. A good first approach is to contour fracture frequency on each level. Areas where data cannot be obtained from core holes can often be supplemented by mapping underground drifts and pit faces. Commonly, extrapolation is necessary, and this can lead to more sophisticated methods of estimation techniques, such as the geostatistics used in ore reserve estimation.

Simulation

After areas of similar fracture frequency have been defined, simulation of the fracturing in the rock mass can be done using Monte Carlo sampling of orientations and spacings. Block sizes can be calculated if all fracture lengths are assumed continuous, which is not a bad assumption because fractures are extended during the blasting. This type of simulation has been done to predict cavability for block caving (White, 1979). A simulation requires good input data, which includes nearly complete knowledge of the fracture orientations and the distribution of spacings. This data can be

time-consuming to obtain and often requires special expertise in data reduction.

There are mathematical models that assume equidimensional fragment shape and that consider the probability of a drill hole or mapping line intersecting the maximum dimension of the fragment. This method results in an approximation of a size distribution curve based on fracture frequency. A curve would be estimated for each area defined on the level maps. Again, the mathematics are somewhat complex, and the results should be checked with direct measurement before extrapolation is done.

Direct Measurement

Most mining companies will not have the means or the desire to attempt simulation or mathematical modeling. Even when these methods are used, some direct measurement is still required to confirm predictions. Again, in direct measurement, areas of similar fracture frequency should be defined on level maps. Direct measurement is essentially a large-scale screening of as much tonnage from the muck pile as is feasible. A set of grizzlies or screens or some combination of screens and grizzlies would be constructed and several tests conducted to develop the size gradation curves for each area defined on the level maps.

Another less accurate method might be simply to estimate percentages from the muck pile. This would be a very crude approximation and many inaccuracies could result, but these approximations would still be better than no attempt to quantify the fragmentation and the crushing requirements. Consideration should be given to photogrammetry to assist in the estimation. Franklin, et al. (1988), report on encouraging results using photoanalysis to determine size distribution of blasted rock.

Both direct measurement methods require fracture frequency to be estimated prior to the blast to correlate fracture frequency with the resulting size distribution curve.

The Geotechnical Model

Once rock hardness and fracture frequency with the corresponding size distribution curves have been defined for each level, combining the data into a final rock classification for crushing requirements is done. A final level map is produced with areas defined according to rock hardness and block sizes. The result is a geotechnical model that can be used to estimate hardness, size, and tonnage in the same manner that tonnage and grade are estimated in ore reserve estimation. If a product of, say, less than 5 cm (2 in.) is desired, a tonnage by level which requires further crushing can be measured. It would be possible with this information to determine crushing requirements for each period in the mine life.

LEACHING

The geotechnical model is also useful for estimating the product size that ultimately reaches the leach dump. Recovery in a leaching operation is determined in large part by the amount of surface area on an individual rock fragment or block that is exposed to the leach solutions. If the tonnages of each size material are known, approximations can be made regarding the available surface area. Leach tests can be designed to give a more accurate prediction of expected recoveries. Thus, a more accurate estimation of recovery from the leach system can be made.

6.9 Waste Dumps

6.9.1 Mineral Leaching Technology: Heap—Dump—In Situ Leaching of Minerals

E.E. MALOUF

EXECUTIVE SUMMARY

1) Technically feasible and economically viable hydrometallurgical processes have been developed permitting the recovery of values from low-grade materials that could not be processed economically by conventional processes. The fast-growing accumulation of technical data, from such diverse sources as the alteration of minerals in an ore body, bacteria-utilizing minerals (Malouf, 1968), the formation of minerals by the spewing of metallic compounds from vents in the seabed, followed by the rapid alteration of the minerals by bacteria (Matthews, 1981), and also the rapid alteration of the minerals in the crater of Mt. St. Helens (Matthew, 1981), all contribute to the development of even more efficient processes.

2) The minerals in ore bodies are altered in nature through a continuous ongoing process. The rate and degree of alteration is governed by the availability of oxygen and moisture to the indigenous bacteria that utilize the sulfides as the energy source for the bacterial life cycle (Malouf, 1968).

3) Major factors affecting the alteration of minerals are:

a) Once moisture enters the ore body a galvanic couple is established between dissimilar minerals which results in the galvanic corrosion of the minerals (Shreir, 1963).

b) Presence of oxygen from the atmosphere or dissolved in water accelerates the oxidation of sulfidic materials in the ore body and of ferrous ions to ferric ions by the indigenous bacteria.

c) The amount of fractures in the ore body along with the pores in the minerals control the rate of alteration.

4) Two general classifications of bacteria are involved in mineral alterations and hydrometallurgical processes: one is the autotrophs, both aerobic and anaerobic. These bacteria thrive on inorganic matter, with the aerobes requiring oxygen while the anaerobes can thrive in the absence of oxygen.

The other general classification is the heterotrophic bacteria, both aerobic and anaerobic. The heterotrophs differ from the autotrophs in that they also require organic matter in the development of energy for their life cycle.

The most common and most studied reactions of the autotrophs are the oxidation of sulfides to form metal sulfates and sulfuric acid, as well as the oxidation of ferrous ions to ferric ions, thereby providing a chemical oxidant for the oxidation of the sulfide minerals. Not as much investigation has been made on the heterotrophs as on the autotrophic bacteria, however one reaction that applies to the metallurgical processes is the ability of these microorganisms, in the absence of oxygen, to reduce sulfates to sulfides (Smith and Shumate, 1970; Postgate, 1965; Baas-Becking and Moore, 1961).

5) Oxidation of the sulfide minerals to sulfates, oxides, or hydroxides results in a severalfold increase in the molecular volume of the mineral, which in turn results in the expansion of the fractures and/or pores of the mineralization in the mineralized zone.

6) Mining of mineralized material increases exposure of

the minerals to moisture and the oxygen of the atmosphere, thereby accelerating the oxidation of the sulfide minerals.

7) With the increased pollutants of sulfur and nitrogen compounds in the atmosphere, the bacterial oxidation of sulfide minerals embedded in limestone or dolomite host rocks has been accelerated to the extent that a normally alkaline or basic environment becomes acidic in a period of 30 years, whereas prior to the massive increase in air pollutants, the conversion from basic environment to an acid environment required 300 to 400 years.

8) The use of trucks for building mineral-containing dumps or heaps results in severe surface compaction as to restrict the convective flow of air through the pile of material and prevents the penetration of water or leach solutions into the interior of the dump or heap.

9) Presence of acid-consuming minerals, such as thau-masite, wollastonite, limestone, and/or dolomite, will retard the alteration and subsequent leaching of the minerals. Measurable amounts of metal ions in solution may not appear from beneath the tailings pile, dump, or heap until the environment or condition of the material has changed from a basic or alkaline state to an acidic state. This may require, under natural conditions, approximately 30 years.

10) If retardation of leaching of minerals is required, as the case may be in impounded concentrator tailings, one or more of the following steps could be used:

a) Compaction or sealing the surface of the mineral-containing material to prevent access of moisture and/or oxygen to the minerals.

b) Mix acid-consuming and clay minerals with the mineralized material. Store the mineralized material in an impervious clay basin.

c) Condition the mineralized material with a bactericide, such as iso-thiazolinone chloride, which is effective at very low concentrations.

d) Elimination of all sulfidic and/or organic matter from the material that has to be stored and not leached.

11) In the heap leaching of uranium, gold, or silver ores, the optimum height for the best recoveries of the values are in heaps up to 7 m (22 ft) high. Multiple *lifts* of the mineralized material diminishes recoveries of the contained values.

12) In the heap leaching of minerals containing values other than uranium, gold, or silver, the optimum height economic relationship are heaps up to 10 m (33 ft). Field experience data indicates that when sulfide or oxide mineral-bearing materials are leached in heaps up to 10 m (33 ft), a new *lift* can be placed on the *ripped* surface of the leached heap and leached as effectively as the first heap or *lift*. This technique has been used successfully in multiples of 12 *lifts*.

13) Microorganisms that alter sulfide minerals will, in a short period of time (30 days) once moisture and oxygen become available, evolve a species adapted to the environment created by the specific conditions of the ore body, heap, dump, or tailings area.

14) Laboratory optimum temperature for the autotrophic, aerobic microorganisms has been determined as 35°C

(Torma, 1977). However, species that carry on their life cycle at 85°C have been isolated from hot, humid, mine waste interiors and from hot sulfur-containing springs (Brierly, 1982).

15) Autotrophic, aerobic microorganisms have evolved that will survive acid solutions of pH 1.5 with copper sulfate concentrations of 15 g/L copper (Malouf and Prater, 1961).

16) Biogenic reactions of significance in mineral alterations resulting in hydrometallurgical processes are:

a) Oxidation of sulfides to sulfuric acid and metal sulfates (Malouf, 1968).

b) Oxidation of ferrous ion to ferric ion to form a chemical oxidant that reacts with the sulfide minerals to form metal sulfates and sulfuric acid.

c) Reduction of sulfates to form sulfides (Postgate, 1965).

d) Microorganisms can function in a pH range of 1.5 to 11.

17) Microorganisms, such as *Thiobacillus thioparus* or *concretivorus*, can utilize the sulfur dioxide in the atmosphere to generate sulfuric acid and start the alteration of minerals that might be contained in acid-consuming host rock. These microorganisms function in a pH range of 7 to 11 (Posnjak and Merwin, 1969; Mayling, 1969).

18) Field process development data indicates that major improvement in the recovery of values from minerals can be achieved by preconditioning of the minerals with the lixiviant prior to leaching. The technology involves "wetting" the minerals, to be leached, with a suitable lixiviant of a greater concentration than would normally be used. The wetting of the minerals usually is made in transit as the mineral-bearing materials are moved to the heaps for leaching. The preconditioning increases the overall recovery by (Malouf, et al., 1958, 1962; Riggs, et al., 1978):

a) Starting the leaching reaction while the heap is constructed, thereby providing intimate contact of the lixiviant with the minerals prior to full-scale leaching.

b) Condition entrained solutions in the interstices of the mineralization, thereby accelerating the diffusion of the metallic ions into the leach solutions.

c) Eliminate the precipitated salts that might be in the pores or fractures of the mineralization blocking the entrance of leach solutions.

d) In the case of sulfide minerals, start the molecular volume change of the minerals, which increases the permeability of the mineralized zone to solutions.

e) Establishing the bacteria on the mineral surfaces to effect biogenic alteration of the minerals.

19) Field developments of in situ leaching of minerals have provided data (Malouf, 1971) indicating that:

a) Successful economic recovery of the values from the minerals contained in the block caved portion of an underground mining operation can be achieved (Fletcher, 1971).

b) The use of explosives to rubble an ore body for subsequent leaching has not proven economically feasible. The formation of *finer* in the explosive-formed rubble *blinds* large volumes of the minerals from contact with the leach solutions.

c) Successful leaching operations have been developed by injecting the leach solutions into the mineralization by pressure. Sufficient pressure is used to dilate the pores of the formation without hydro-fracturing the rock (Malouf, 1971).

20) Pad construction for the recovery of leach solutions from under heaps of mineralized material involves the following factors:

a) In all cases, a minimum flow gradient of 5% from under the heap to the collection reservoir.

b) Removal of all vegetative or organic matter from the area to be overdumped to prevent the contamination of the leach solutions with organic compounds that might affect subsequent solvent extraction processes.

c) A compacted subsurface overlain with a minimum of 0.5 m (18 to 20 in.) of compacted clay. The clay pad is to be constructed in a minimum of three increments.

d) A compacted subsurface overlain with a minimum 15 cm (6 in.) asphalt-compacted surface. The asphalt pad must be protected with a sand or tailings impact cushion of material before construction of the heap.

e) A more recent concept in pad construction that is proving to be more effective than other types of construction is a chemical pad. The pad is constructed by placing 5 to 7 cm (2 to 3 in.) of compacted crushed limestone onto a compacted graded area that is to be used as the heap site. The compacted, crushed limestone is then sealed with a solution of ferric sulfate.

The particular advantage of this type of pad is its ability to self-heal any cracks or fissures that might develop from subsidence. This is the case if the leach solutions contain ferric ions.

21) Current research and development efforts on the elimination of cyanide anions from leach solutions to be discharged from gold and silver leaching operations have provided a new commercial approach. Data has been developed indicating that microorganisms, usually indigenous to the leaching operation, utilize the cyanide compounds as their energy source, producing nitrogen and carbon dioxide as the end product. One such microorganism is *Thiobacillus cyanoxidans*.

22) Biogenic mineral reactions can be used to process sulfide-bearing gold ores to alter and eliminate the sulfide minerals, leaving the gold available for recovery by conventional cyanide leach solutions.

INTRODUCTION

Hydrometallurgical processes for the recovery of values from minerals are controlled and accelerated reactions similar to the reactions found as continuous natural oxidation and leaching occurring in nature. Current studies provide data indicating that as soon as minerals are formed, bacteria are rapidly altering them, as has been observed around the vents in the seafloor and in the volcanic crater of Mt. St. Helens (Matthews, 1981). A common denominator, apparent through the study of various mineral deposits, indicates that all mineral deposits that have natural oxidation and leaching have the following zonal generalizations:

Leached capping zone.

Secondary enrichment zone.

Primary mineralization zone.

Roll-front accumulation of reduced metallic ion compounds that on oxidation become soluble compounds, such as the uranium mineralization found in sandstone formations. Some copper, molybdenum, and vanadium compounds are also found in such formations.

Data from the examination of leached capping rock specimens from various ore bodies indicate the presence of fossil imprints of minerals that have been leached. These observations have been made to a depth where the ancient water table had sealed the area to further oxidation. At the point where oxidation is prevented by the water table, a reduction zone results that precipitates the previously leached metallic ions into insoluble compounds, which combined with the minerals in the zone, result in secondary enrichment.

Once the mineralized sulfide material is placed into dumps, heaps, or tailing areas, the oxidation of the sulfides

again occurs and the formation of water-soluble metal sulfates is accelerated by the availability of oxygen, water, and bacteria. The bacteria are usually indigenous to the ore body.

Data from examination of samples obtained from massive mine waste dumps and concentrator tailings ponds indicate that natural oxidation and leaching of the sulfide minerals occurs and the sulfuric acid generated by the oxidation of the sulfide minerals leaches the oxide minerals, even without the application of leach solutions. The moisture from rain and/or melted snow along with oxygen from the atmosphere is sufficient to establish the autotrophic, aerobic microorganisms that oxidize the sulfide minerals and form water-soluble metal sulfates.

Data obtained from samples from the interior of massive mine waste dumps indicate that areas deficient in oxygen, usually 50 m (150 to 160 ft) below the surface, show zones of secondary enrichment in the case of copper mineralization.

The following lists some of the reactions during the natural leaching of a copper sulfide ore body:

Leached Zone (Oxidation and Acid Generation)

Leaching Zone (Oxidation and Solubilization of Copper Sulfides)

Enrichment Zone (Reduction and Neutralization)

In the natural alteration and leaching of sulfide minerals, the following principal reactions involving the generation and/or consumption of acid occur. These reactions are of major importance in the design of hydrometallurgical processes.

Generation of Acid:

Oxidation of sulfides, particularly pyrite.

Hydrolysis and precipitation of ferric sulfate.

Consumption of Acid:

Oxidation of ferrous sulfate.

Acid attack or dissolution of gangue minerals (such as biotite, carbonates, and calc silicates).

Dissolution by acid of precipitated salts of iron, copper, aluminum, silica, and uranium.

Some typical chemical reactions showing the generation and consumption of sulfuric acid in both natural and applied hydrometallurgical processes are as follows:

1) Oxidation of sulfides to generate sulfuric acid

Chalcopyrite

b) Pyrite

2) Consumption of sulfuric acid

a) Bacterial oxidation of ferrous ion

b) Gangue mineral reactions with sulfuric acid

(biotite)

3) *Hydrolysis and precipitation of ferric iron salts* will release sulfuric acid to the solution according to the following reaction:

The foregoing reactions are common to the various copper mine waste leaching operations and constitute the source of sulfuric acid that contributes to the leaching operation success.

HEAP OR DUMP DESIGN FOR ENHANCEMENT OF MINERAL LEACHING

Major factors affecting the leaching of minerals are:

Aeration is a most critical factor where the material to be leached contains sulfide minerals. Convected air supplying the required oxygen to the autotrophic aerobic bacteria will penetrate the face or sides of a dump or heap for a distance of approximately 65 to 70 m (200 ft). For the convection of air to occur it is necessary that the surface compaction of the dump or heap be removed. The compaction on the surface of a dump or heap occurs from the action of the truck tires on the material by the trucks bringing the mineralized material to the dump or heap. Compaction measurements made on a dump by 65-ton trucks indicate compaction occurs to a depth of 3 to 4 m (12 ft), with the upper 0.6 m (2 ft) constituting the most severe compaction. This compaction measurement gave approximately the same data as rock in place. Also the upper 0.6 m (2 ft) of compaction contained considerable *fines* formed by the grinding action of the truck traffic on the material.

Size of the heap or dump is a critical factor in the successful recovery of the values by leaching. Again, if the minerals to be leached are sulfides, the width of the heap or dump should be limited to 130 to 140 m (400 ft), as the convection of air supplying oxygen for the oxidation of the sulfide minerals will penetrate the sides of the heap or dump approximately 65 to 70 m (200 ft).

Field data also indicates that convection of air through a porous surface of a heap or dump will penetrate the pile approximately 15 to 20 m (50 ft); below this depth reducing conditions will become established.

A 12 to 15 m (35 to 50 ft) depth of material in a heap or dump should be leached before a new *lift* of material is placed on the heap or dump.

A third factor involves the composition of some of the barren rock being moved into the heap or dump during the mining operation. If this material contains acid-consuming minerals, such as thaumasite, wollastonite, or limestone, the solubilized metals will be precipitated and adsorbed by these minerals. These minerals should be selectively mined and disposed in areas outside of the heap or dump to be leached.

A fourth factor is the size of the material placed in the heap or dump. If the material is too coarse, a lower recovery can be expected as a longer leaching time will be required. Solution channels will be established that will prevent leach solution contact with all of the mineralized material for the

time needed to achieve high recovery of the mineral values. During a mining operation of material to be leached, it may be possible to use *ripping* of the ore or extra explosives to fracture a greater amount of the ore.

In summary, mined ore should be classified into three general classifications:

Mineral-barren material, and/or material containing high acid-consuming minerals or clay; all of these materials should be kept out of a heap or dump that is to be leached.

Materials containing economic quantities of minerals that justify the cost of constructing proper heaps or dumps for the leaching of the minerals.

Materials containing uneconomic quantities of minerals should be disposed of in areas not suitable for leaching.

Heap or Dump Construction

Current technology in heap and/or dump construction successfully practiced for the recovery of such values as copper, gold, silver, and uranium is as follows. The same approach is applicable to all minerals to be leached; the processes differ in the leach solutions used. The common basis of construction is:

Construction of the heap and/or dump in a drainage basin that has a flow gradient or slope exceeding 5%.

An ideal location for construction is in an area where the bedrock is near the surface. This will result in good leach solution recovery at a minimum cost. If permeability data of the area on which the heap and/or dump is to be constructed indicates that leach solutions might be lost subsurface, the area must be made impervious to leach solutions. This can be accomplished by one of the following methods:

Remove all organic matter from the area. Grade and compact the area to obtain an uninterrupted flow gradient to a collection dam on bedrock.

If the area is overlain with 2 to 3 m (6.6 to 9.8 ft) of alluvium, no further action will need to be taken. Otherwise, the area must be covered with a compacted layer of 0.5 m (1.5 to 2 ft) of clay or river-bottom silt containing clay.

The compacted clay pad is then covered with 1 m (3.3 ft) of coarse rock to achieve good drainage of solutions from beneath the heap or dump and to provide an impact cushion of material to protect the pad during construction of the heap or dump.

A second approach is to use a 15 to 18 cm (6 in.) asphalt layer as a pad on the cleared, graded, compacted area. The same steps must be followed to protect the pad with a cushion of material during the construction of the heap or dump.

An asphalt pad, from field data, appears to lose some of the imperviousness (approximately 50%) after six to seven years of service.

A more recent development is the formation of an impervious base to a heap or dump by placing a 5 to 7 cm (2 to 2.8 in.) compacted layer of crushed limestone onto the cleared, graded, compacted area. The crushed limestone is then sprayed with a strong solution of ferric sulfate. The chemical coating forms a very impervious membrane.

If the leach solutions percolating through a heap or dump contain ferric ions, the pad under the heap or dump will continue to build up in accumulated ferric salts. In fact, fissures or cracks that might develop after a heap or dump is built would be *healed* in this manner.

Removal of all vegetation or organic matter from the area to be overdumped is necessary, because the organic products that would be picked up by the leach solutions would affect the solvent extraction operation.

The width of the heaps or dumps containing sulfide min-

erals should be limited to 120 m (400 ft), or less, thus allowing the maximum width that still supplies air by convection. The oxygen of the air is required for oxidation of the sulfide minerals.

If the heaps or dumps are constructed by moving the material by trucks, the upper 0.5 m (18 in.) should be removed. The *finer* generated by the action of the truck wheels on the material not only will affect the application of leach solutions but also will restrict the convective flow of air through the material.

After the removal of *finer* from the surface of the heap or dump, the surface must be *ripped* to a depth of 2 to 3 m (6.6 to 9.8 ft) in one direction, on 1-m (3.3-ft) centers, followed by *ripping* the surface again at right angles to the first series of rips. The action of ripping the surface of the heap or dump is to reestablish the pervious nature of the surface, which becomes compacted to a density of rock in place by the pounding action of the loaded trucks.

A technique that permits increasing recoveries of values from the leached minerals from a nominal 25 to 45% over a period of years to recoveries of 65 to 75% in a period of months involves *wetting* of the mineralized material with preconditioning solutions (Malouf, et al., 1958, 1962; Riggs, et al., 1978). In the case of leaching copper oxide minerals, the preconditioning solutions could be strong acid solutions containing 50 to 200 g/L of sulfuric acid. The amount and strength of the acid solutions is determined from laboratory and pilot plant test data. In the case of the leaching of silver- or gold-bearing materials, the preconditioning solutions could be varying concentrations of cyanide solutions or thiourea or thiosulfate solutions (Torma, 1977).

Heights of heaps or dumps containing copper minerals should not be greater than 10 to 15 m (35 to 50 ft). After leaching has been completed on the *lift* of material, additional *lifts* can be placed on the leached material. The multiple lift concept appears to function suitably in the field up to an overall height of 48 m (150 ft). In the heap or dump leaching of uranium, gold, or silver, field data indicates that loss of recovery appears after the height exceeds 6 to 7 m (20 ft).

Leaching Operation

Successful commercial leaching operations are being made in the recoveries of copper, uranium, gold, silver, potash, and sodium chloride.

The leaching of copper minerals usually is done with solutions made acidic with sulfuric acid. The effluent solutions from the leaching operation contain iron, aluminum, magnesium, and silica in concentrations ranging from 2 to 8 g/L. No effort as yet has been made to recover the aluminum or magnesium from the leach solutions, even though the concentration of each of these metals is in the range of 6 to 8 g/L.

The copper-bearing solutions usually are processed by concentration of the copper ions in a solvent extraction plant and electrowinning the copper from the concentrated solutions (Ashbrook, 1973). The use of the copper cementation process or the precipitation of copper on metallic iron is being used less and less because of the increasing cost of the metallic iron scrap for this purpose, the loss of the residual acid in the leach solutions, and the deleterious effects of the iron salts precipitating on the surface and in the interior of the heaps and dumps, thereby preventing solution contact with the minerals.

Leaching of heaps containing gold and/or silver values is accomplished with alkaline-cyanide solutions. The pregnant silver- or gold-bearing solutions are passed through

columns of activated charcoal to absorb the values on the charcoal, followed by stripping the values from the carbon and recovery by electrolysis. In the case of strong silver-bearing solutions, the Merrill-Crowe process of precipitation with metallic zinc is used (McQuiston and Shoemaker, 1981).

No commercial attempts have been undertaken as yet to leach gold or silver values using thioureas or thiosulfate compounds (Torma, 1977).

Leach Solutions

The most commonly used leach solution in the leaching of copper minerals is made from the tailings solutions from a copper cementation operation or the raffinate from a solvent extraction operation, along with sufficient makeup water and sulfuric acid to adjust the pH of the leach solutions to the desired level. Makeup water is required to replace water or solutions lost to evaporation and/or seepage during leaching. The pH is controlled to buffer the various salts in the recycled solutions, to provide sufficient acidity to keep the leached copper salts in solution (pH 2.4 or lower), and to control the hydrolysis and precipitation of ferric ions in the pipelines, surface, and interior of the heap or dump. Occasionally, deposition of ferric iron salts in the interior of a heap or dump has developed to a degree that solutions are impounded in the interior and hydraulic rupturing of the side of the heap or dump occurs.

Controlling the pH of the leach solutions at pH 2.4 or lower will prevent the necessary microorganisms from becoming encapsulated in precipitated iron salts.

Methods of Leach Solution Distribution

Some of the more successful leaching operations control the distribution of the leach solutions to the surface of the heaps at the rate of 5 to 6 L/h/m² (0.1 to 0.2 gal/sq ft/hr).

The solutions may be distributed in one of several methods. One of the cheapest and most effective methods was developed by the Cyprus-Bagdad copper leaching operation at Bagdad, AZ. It consists of placing 0.5 m (18 in.) long pieces of surgical tubing 0.1 cm ($\frac{3}{8}$ in.) in diameter. These pieces of tubing are attached to nozzles from a 2.5-cm (1-in.) diam plastic pipe at 2.5 m (8 ft) intervals. Using solution pressures of 25 to 377 kPa (40 psig), a portion of the heap surface 3 to 4 m (10 to 12 ft) in diameter is *wetted* uniformly.

Plastic sprayers or *rainbirds* with stainless steel return springs are used for the effective distribution of leach solutions.

In arid climates, consideration should be given to using injection trickle tubes. The trickle tubes can be inserted in shallow drill holes that penetrate the compaction of the surface of the heap.

A natural segregation of the coarse and fine material occurs as a heap or dump is constructed. Furthermore, bulldozer leveling of the surface will cause additional segregation of the material. The overall effect is to form alternate layers of coarse and fine material in the heap or dump. The leach solutions follow a path of least resistance in passing through the material, leaving portions of the mineralization untouched by the leach solutions. Due to this, heaps and dumps should be built as uniformly as possible to assure maximum solution contact with the minerals to be leached, thereby assuring the highest recovery possible. If the material being placed on the heap or dump contains an excess of fines (+15%), agglomeration of the fines to the coarse material should be undertaken prior to placing the material in the

heap or dump. The foregoing conditions apply to all types of materials that are leached, whether to recover copper, uranium, gold, or silver.

PROCEDURES FOR LABORATORY AND FIELD TESTING OF LEACHING MINERALS

Introduction

Laboratory and pilot plant data are required to determine the technical and economic feasibility of leaching values from mineralized rock, and in the case of disposal of mine or concentrator tailings material, the amount of possible pollutants that might need to be removed from the natural leaching solutions generated by rain or melted snow.

Design of the laboratory and/or pilot plant heap tests must be based on the intended results, namely:

1) Mineralized material to be leached for the maximum recovery of the contained values in the least possible time.

2) Mineralized material to be leached does not contain the values to sustain the cost required in No. 1, but leaching is to be accomplished at moderate cost.

3) Mineralized material to be leached at minimum cost, irrespective of recovery.

4) To establish the amount of pollutants that will be leached naturally from the mineralized material contained in the mine waste and/or concentrator tailings material.

The column size, heap size, and particle sizes would be applicable to any mineralized material to be leached. The changes from one mineral type to another would involve details of operation, such as lixiviant, whether *finer* should be removed or agglomerated, whether the minerals should be preconditioned with the lixiviant, and control of the salt content of the leach solutions.

Under the conditions outlined in No. 1, consideration has to be given to the possible added costs of crushing, agglomeration, and preconditioning, if required.

Under the conditions outlined in No. 2, leaching would be made without the costs of crushing, agglomeration, and possibly preconditioning.

In case No. 3, leaching would be made at a minimum cost. This would involve pumping the value-stripped solutions back onto the heap or dump, without the costs of special preparation of the mineralized material or the costs of solution adjustment of buffering the pH and salt content.

In case No. 4, accelerated laboratory column leach tests would need to provide data on the amount of polluting salts that might need to be processed to prevent pollution problems.

Successful extrapolation of the data from 1-t (0.9-st) column leach tests have been made in determining the recoveries and grade of solutions that might be expected from a commercial operation. This type of test involves obtaining 1 t (0.9 st) of representative ore that has been coarse crushed to -4 cm (-1½ in.). If the sample contains fines in excess of 15% of the total weight, agglomeration of the fines with the coarse fraction of the ore should be made before the sample is placed into the column. A column 0.5 m (20 in.) in diam by 3 m (10 ft) high is suitable to contain the sample.

Procedure for Test Column

The column is loaded with approximately 1 t (0.9 st) of the representative, thoroughly mixed crushed ore, without permitting segregation of the fines and coarse fractions. A perforated plastic plate in the bottom of the column can be used to support the sample. The surface of the column of ore is covered with an open weave nylon cloth to provide

uniform distribution of the leach solutions over the surface of the material.

If the test is to be conducted to achieve the maximum recovery of the values in the least possible time, a preconditioning solution is applied to the material. The conditioning solution is usually of the same composition as the lixiviant that is to be used during the leaching, with the exception that the preconditioning solution is of a greater strength (four- to tenfold) than the normal leach solution.

The preconditioning solutions are allowed to penetrate the mineral pores, fractures, and interstices, thereby starting the reactions that result in the alteration of the minerals into water-soluble compounds.

A preconditioning-reaction period of 10 to 14 days is allowed before systematic leaching is started. The volume of preconditioning solution to be applied to the column of ore is equivalent to one pore volume displacement of the material in the column.

Leach solution application rate to the surface of the column of ore is 5 to 7 L/h/m² equivalent (0.1–0.2 gal/sq ft/hr). The solutions passing through the column of material for each 24-hr period are sampled. The sample of solution is analyzed as to pH, volume, temperature, and various salt and values content.

At the end of leaching, the column of mineralized material is washed with a displacement volume of leach solution, equivalent to 20% of the material weight.

The leached material from the column is then removed, dried, weighed, and crushed to (–2mm) (–10 mesh). Then it is sampled and analyzed for the remaining values to establish a metallurgical balance (McQuiston and Shoemaker, 1981).

IN SITU OR IN PLACE LEACHING OF MINERALS

Introduction

The development of in situ leaching of minerals has followed approaches of:

In place leaching, which involves the application of leach solutions to *caved* or *stoped* areas of an underground mine. The leach solutions are applied to the broken ore and recovered in the underground galleries of the mine.

In place leaching, wherein the ore to be leached has been broken by explosives, after which the leach solutions are applied to the broken ore.

In situ leaching, wherein the leach solutions are injected into the mineralized rock by controlled pressure. The leach solutions follow the strike, dip, and fracture set of the ore body to be recovered down dip in the ore body.

In situ leaching, wherein the ore is *hydrofractured* or *explosive-fractured* before injecting the leach solutions.

Commercial Applications

Several successful commercial in place leaching operations have been established in copper and uranium ore bodies. In these operations, *block-caving* mining techniques were used to obtain ore for conventional processing in a concentrator. After underground mining became unprofitable, the remaining *caved* ore in the mine was leached by percolating the leach solutions from the surface of the *caved* area down through the broken ore to the production galleries beneath the *caved* area. The value-bearing solutions are recovered on the impervious base of the collection galleries, pumped to the surface for processing to recover the values, and the barren solutions are adjusted as to the chemical content and recycled to the *caved* area.

A classical example of in place leaching is the copper leaching operation of the Miami Copper Co. at Miami, AZ (Fletcher, 1971). An abstract of this operation is: By 1955, the conventional mining by underground *block caving* to obtain ore for the concentrator had become unprofitable. Leaching of the *caved* ore was attempted and proved economically successful. The procedure consists of applying pH 1.9 acidified leach solutions to a portion of the surface depression caused by the *caved* material, allowing the leach solutions to percolate downward approximately 300 m (1000 ft) of mineralized material into the old established production galleries of the mining operation. When the copper content of the effluent solutions dropped to a predetermined level, the solutions on the surface of the *caved* area are moved to a new section. The previously leached area is allowed to oxidize approximately one year before leach solutions are again applied to the area. Approximately 680 kg (1.5 million lb) of copper per month have been produced in this manner since 1955.

Criteria for the successful implementation of in place leaching are:

The mineralized material must be of a rock type that will readily *cave*.

A minimum of 25% of the ore body must be mined to provide sufficient void space to achieve proper *caving* of the mineralized material.

An impervious shale or a very dense rock base of uniform gradient should underlie the mass of *caved* material to achieve good solution recovery of the value-bearing solutions.

Recovery galleries or solution recovery well points must be below the water table.

If sulfide minerals are present in the *caved* material, oxygen from air flow through the material must be maintained by positive air pressure in the material.

Other successful in place commercial leaching operations involve leaching of uranium from the stopes and *caved* areas of underground uranium mines. Uranium is leached by spraying the underground workings with acidified ferric sulfate solutions that oxidize the insoluble four valent uranium ion into a water soluble hexavalent ion (Schlitt and Shock, 1979).

In situ leaching of uranium from sandstone formations is a continuing successful practice. This technique requires that the ore body be underlain with an impervious shale, clay, or dense rock formation beneath the water table, thereby permitting the recovery of the value-bearing solutions. Patterns of injection wells and recovery wells are designed for each ore body to achieve good solution contact with the mineralization as the solutions flow to the recovery wells.

In situ leaching of copper from the periphery of a mined-out open pit copper mine has been accomplished by pressure injection of the leach solutions into the mineralization. Successful operation on a semi-commercial scale was accomplished by taking advantage of the naturally highly fractured nature of the ore body, along with the strike and dip of the ore body to control the flow of the leach solutions to the recovery point (Malouf, 1971).

Rubblization with explosives of an ore body followed by leaching has proven to be uneconomic. Three different attempts to rubblize an oxide copper deposit with explosives and leach the copper from the rubblized material on a commercial scale have been made in the United States. In all instances, the amount of fines (+20%) generated during the rubblization *blinded* a large proportion of the material from solution contact. Recoveries approximating 17% over a three-year period were achieved before further leaching was abandoned.

In summary, observations and studies made on in situ leaching of minerals indicate that the successful operation is controlled by:

The mineralization must be in a sandstone formation or a highly (naturally) fractured rock, with little or no clay minerals.

The ore body must be underlain with a uniform, dense shale, clay, or rock that would be impervious to leach solutions.

The solution recovery zone must be below the water table and have a uniform gradient or dip to a recovery point to minimize the cost of solution recovery while maximizing the recovery of values.

6.9.2 Design and Operating Considerations for Mine Waste Embankments

M. K. McCARTER

INTRODUCTION

Waste embankments occupy a substantial portion of the area required for surface mining. Specific mines may have individual embankments in excess of 300 m (984 ft) high and volumes in excess of 500 Mm³ (653 million cu yd) of material (Campbell, 1981). Such structures represent a significant investment in both monetary and energy resources. Subsequent to construction, waste embankments usually have little if any practical use and may represent a long-term liability in the form of a potential source of pollution or stability hazard. Because of economic considerations and potential environmental impacts, waste embankments must be carefully engineered.

The word *dump* is commonly used throughout the mining industry in place of waste embankment and describes the mode of deposition rather than unsanitary or unsightly conditions. In coal operations, such structures may be referred to as tips, signifying the point where rail conveyances are tipped to discharge their contents. Both words should be considered as having similar connotations.

In the past, little consideration was given to selecting optimum dump sites (D'Applonia, 1977?). The rule of thumb was to dump waste occurring in the upper levels of a mine at high elevations and low waste at low elevations while minimizing the distance traveled. This procedure often minimizes immediate cost of waste disposal, but if used indiscriminately can result in expensive rehandling and adverse environmental impact. The Surface Mining Control and Reclamation Act of 1977 and subsequent state and federal legislation have added new dimensions to waste dump planning. At present, greater effort must be expended to properly site dumps to mitigate environmental effects and promote long-term reclamation. This section will briefly summarize essential concepts in siting, operating, and maintaining rock fills deposited by trucks, scrapers, rail cars, and conveyor belts.

WASTE DUMPS CLASSIFICATION

Waste dumps are broadly classified as water-impounding or nonimpounding. If the dump is situated across natural drainage so as to allow continuous or intermittent accumulation of water or saturated waste behind the structure, it is classified as impounding. If water cannot accumulate, it is classified as nonimpounding. Structures may retain interstitial water or impede percolating water and still maintain the nonimpounding status. Siting of impounding facilities requires consideration of the magnitude of future precipitation events, sedimentation control, and design of out-flow structures. In this respect, design of impounding structures requires more effort than the less complicated nonimpounding structures. The present discussion will focus only on nonimpounding dumps. Further information pertaining to impounding structures may be found elsewhere (D'Applonia, 1977?; Anon., 1971, 1974).

Rock dumps constructed in the process of surface mining commonly are composed of *durable rock* or *hard rock*. Hard rock is defined in 30 CFR 816.74 as "... rockfill consisting of at least 80 percent by volume of sandstone, limestone, or other rocks that do not slake in water." (See Brown, 1981 for a description of slaking tests.) Such materials are expected

to remain relatively inert and provide perpetual permeability of the gross structure. Materials that comply with slake durability as defined by the applicable regulatory authority can be deposited in single-lift structures. Coal waste that does not meet this criteria must be deposited in multiple compacted layers. Normally, regulations pertaining to coal are more stringent than those governing deposits of copper, gold, iron, molybdenum, etc. If a question exists concerning acceptable engineering practice, the engineer can usually be assured of a conservative design by adhering to the regulations for coal waste as defined in Title 30 Code of Federal Regulations.

In addition to impounding and nonimpounding status and durable vs. nondurable material, waste dumps can also be classified according to configuration, composition, and environmental sensitivity (Taylor and Greenwood, 1985).

Configuration

Natural topography provides several options for siting dumps. The dumps may be placed on relatively level ground, in valleys, on side hills, or along ridge tops. The location provides a corresponding adjective that is helpful in creating a mental picture of the structure.

Heaped: A heaped or fan dump is constructed on relatively flat terrain (Couzens, 1985). The final elevation of the crest of the dump may be achieved by compacting successive layers of fill with interconnecting ramps established between the original ground elevation and the current lift (Fig. 1). Alternatively, the structure can be completed by extending the top of a ramp laterally in a single lift (Fig. 2). If the lift is long relative to its width, it is referred to as a *finger dump*.

Valley Fill: Waste may be placed in a valley by continuous dumping on the downstream face from the planned final elevation. Valley fills may also be constructed from the bottom up using compacted lifts. The latter construction is more expensive and occasionally more hazardous in that steep downhill grades may be necessary to bring waste to the final elevation. The level surface of the dump is normally graded toward collection channels on the lateral boundaries or to a rock-core chimney drain established at the center of the dump (see 30 CFR 816.73).

A true valley fill is constructed below the ridge line separating the construction site from adjacent canyons (Fig. 3). If the valley fill is constructed to completely fill the disposal site to the elevation of the ridge line, the structure is more properly identified as a head-of-hollow fill (Fig. 4). If the dump extends from one side of a drainage channel to the opposite side in the shape of an earth dam, it is referred to as a cross-valley fill (Fig. 5). Such structures can be made temporarily nonimpounding by placing culverts in the drainage as part of the construction process. Maintaining a perpetual nonimpounding status for cross-valley fills is a difficult task in that metallic culverts and other open conduits are easily plugged by debris and may have a short life expectancy.

Side-Hill Fill: A very common practice in noncoal surface mines is to construct dumps over existing slopes (Fig. 6). Construction is normally accomplished by allowing the material to freeflow down the slope from a predetermined crest elevation. Side-hill fills may also constitute the first

Fig. 1. Heaped dump constructed in successive layers.

construction phase for valley fills. Occasionally side-hill fills are referred to as wedge dumps (Couzens, 1985).

Ridge Fills: Embankments of this type are placed at a ridge crest so that material is deposited on both sides of the divide (Fig. 7). Ridge fills may be thought of as back-to-back side-hill fills.

Composition

Taylor and Greenwood (1985) identify four categories that can be used to identify the potential impact of mine wastes on biological systems and the environment in general. The categories are (1) nonhazardous/hazardous, (2) inert/reactive, (3) fugitive dust susceptible, and (4) leachate susceptible.

Nonhazardous/Hazardous: Section 1004(5) of the Resources Conservation Recovery Act classifies material that presents a substantial potential threat to human health or the environment as hazardous. Few, if any, overburden materials fit this classification unless they contain radioactive substances, soluble toxic compounds, or have been treated with chemicals such as cyanide or similar reagents.

Inert/Reactive: An inert material exhibits no chemical reactivity under normal environmental conditions. A reactive material, on the other hand, can undergo chemical change at normal temperature, moisture, and oxygen levels. Waste containing iron pyrite would be a good example of a reactive material.

Fugitive Dust Susceptible: This category is applied most frequently to mill tailings but can describe overburden waste that contains a high percentage of dust size particles. Such windborne material can restrict visibility and occasionally present a health hazard for individuals working in the immediate area.

Leachate Susceptible: Susceptibility to leachate action

is closely related to processes involved in the inert/reactive category. Leachate susceptibility, however, may not involve chemical reactions. Substances may simply be soluble in aqueous solutions. The term leachate susceptible also implies a degree of permeability for the waste material. Not only must soluble materials be present, but the fill must allow infiltration and migration of solutions before adverse environmental consequences occur.

Environmental Sensitivity

The impact of a mine waste dump is directly proportional to the sensitivity of the environment in which the structure is located. Taylor and Greenwood (1985) offer a relative scale of sensitivity based on hydrologic, climatic, ecological, or social/political consequences. A dump located below a large watershed or in an area of high annual precipitation will be more vulnerable to flood flows and solution activity than one located in a dry climate. A dump located above a flood plain could impact water users downstream to a greater extent than a dump at a lower elevation. A dump located in the vicinity of abundant wildlife and vegetation would certainly have a higher environmental sensitivity than a similar structure located in a barren area. And finally, a dump located near communities or industrial facilities would have a higher sensitivity classification than one located in a remote area.

Taylor and Greenwood (1985) have proposed an alphanumeric classification for coal waste that incorporates factors describing impounding, configuration, composition, and sensitivity status. This scheme probably has much utility for regulatory purposes, but is of less value to engineers who need a more generic description. It is important to remember, however, that the foregoing factors need to be assessed in any complete description of a dump site.

Fig. 7. Ridge fill.

REGULATIONS

Siting of waste dumps in the United States is subject to regulatory control in the form of permits, design specifications, or design approvals. It is necessary for the engineer to become familiar with specific requirements by referring to the appropriate state and federal documents. Table 1 provides a listing of the various federal acts and the subjects with which they deal. Within the federal government, responsibility for approving mining plans rests with the agency assigned to manage the surface at the given location (e.g., Forest Service, Bureau of Land Management, Bureau of Indian Affairs, or Bureau of Mines-OSM). In addition, responsibility may be governed by the mineral commodity (e.g., locatables, leasables, or salables). Consequently, more than one federal agency may be involved in approving plans for a waste dump. In general, a federal, state, or local authority will approve or adopt the regulations of another legal jurisdiction provided the regulation is more stringent than its own. Where several agencies are involved, a joint review process may be implemented, allowing one agency to conduct approval processes for all (Vandre, 1985).

Requirements specified in the various regulations are designed to prevent adverse consequences and are generally conservative. The fact that a waste dump complies with all regulations, however, does not eliminate the possibility of future legal problems involving adjacent land owners. For this reason, the engineer should fully evaluate the risks involved in siting a specific dump and incorporate appropriate mitigating measures in the embankment design. For example, specific regulations require a safety factor of 1.5 for waste embankments associated with coal operations. If a particular dump is to be located uphill from a community (high environmental sensitivity), the engineer should carefully choose the "acceptable" technique for stability analysis and critically review how representative the laboratory and field data are. If uncertainty exists, it may be appropriate to raise the design safety factor above that required by the regulations.

A brief summary of general design requirements contained in the Surface Mining Control and Reclamation Act is provided in Table 2. These regulations are specifically for excess spoil associated with coal mining; however, obvious parallels do exist for dumps associated with other types of deposits.

SITE EVALUATION

Four steps are easily identified in selecting the optimum site for a waste dump:

1. Locate potential dump sites well beyond the surface intercept of the ultimate pit.
2. Rank available sites according to capacity and haulage cost per ton.
3. Evaluate geotechnical and hydrologic suitability of sites exhibiting acceptable capacity and minimum cost.
4. Estimate reclamation and mitigation costs if substantially different construction methods are to be used in the alternative sites.

The first step appears obvious but in reality is not easily accomplished. Generation of the ultimate pit surface is an ongoing engineering responsibility. As economic conditions change, the position of the ultimate intercept may also change. As a consequence, attempts to minimize immediate costs through short haulage profiles may be offset by the need to rehandle waste placed too close to the open pit. Some planning engineers establish a zone 100 m (328 ft) wide or more beyond the ultimate intercept in which no permanent facilities are placed.

Frequently the first two steps will clearly identify which site is optimum. Occasionally two or more alternatives will exhibit closely competing total hauling cost. In this case, environmental sensitivity and the cost of environmental impact mitigation and reclamation should be considered along with haulage cost.

Previous sections have described procedures for calculating haulage cost for a given profile. The profile for waste haulage begins at the centroid of the volume of material to be removed and ends at a point representing the average position of the dump crest for the planning period. The position of the crest as a function of time can be obtained by arbitrarily drawing a crest position within the dump limits and calculating the corresponding volume and tonnage. The time to bring the dump crest to the trial position is obtained from the average waste production assigned to that dump. Successive trial positions are assumed until the planning period is bracketed. The average crest position can then be estimated by eye.

The density of implaced waste is a function of initial swell of excavated material relative to the bank density and the recompaction of loose material in the embankment. Common earth materials will swell from 10 to 60% of their original volume when excavated (Gessel, 1981). In hard rock operations, the swell is typically between 30 to 45% (Bohnet, 1985). Compaction is a function of material type, size distribution, and placement method. Factors are variable and can range as high as 25% relative to bank conditions. Com-

Table 1. Summary of Legislation Affecting Mine Waste Dumps*

Subject	Act or Statute
Environmental analysis	National Environmental Policy Act of 1969 (NEPA) 42 USC 4321 et seq.
Water pollution	Federal Water Pollution Control Act Amendments of 1972, Clean Water Act of 1977, Clean Water Act Amendments 1978 33 USC 1251 et seq.
Control of solid waste	Resource Conservation and Recovery Act of 1976 (RCRA) 42 USC 6901 et seq.
Health and safety	Federal Coal Mine Health and Safety Act of 1977 30 USC 951 et seq.
Operation and reclamation	Surface Mining Control and Reclamation Act of 1977 (SMCRA) 30 USC 1201 et seq.
Hazardous waste	Toxic Substances Control Act (TSCA)

Table 2. Required Specifications for Excess Spoil

Specification	Reference
Leachate and surface runoff must not degrade surface or ground waters	30 CFR 816.74-1
Fill must be designed using recognized professional standards and certified by a registered professional engineer	30 CFR 816.74-3b
All vegetative and organic material must be removed from the disposal site prior to dumping	30 CFR 816.74-3c
Slope protection in the form of riprap or vegetation must be provided on all disturbed areas to minimize surface erosion	30 CFR 816.74-3e
Disposal areas must be located on the most moderately sloping naturally stable areas	30 CFR 816.74-3e
No depressions or impoundments will be allowed on completed fills (exception noted for head-of-hollow fills, 30 CFR 816.73)	30 CFR 816.74-3g
Fills are not to be constructed on natural terrain where the slope exceeds 36% unless special provisions are made to insure stability	30 CFR 816.74-3i
The fill must be inspected quarterly by a registered engineer or qualified professional specialist	30 CFR 816.74-3j
If the disposal area contains water courses, springs, or seeps, an underdrain consisting of durable rock with suitable filters must be provided	30 CFR 816.74-3l
Investigation and testing of foundation materials for stability analyses must be performed	30 CFR 816.74-3m
Fill placed against a highwall must have a static safety factor of 1.3	30 CFR 816.74-3o,3,iv
Valley fills must have a static safety factor of 1.5 and a safety factor of 1.1 under earthquake conditions	30 CFR 816.72-a
Surface water above a valley fill must be diverted away from the fill in channels designed to safely pass the runoff from a 100-year, 24-hr precipitation event or larger event if specified by the regulatory authority	30 CFR 816.72-d
Horizontal surfaces of valley fills must not slope greater than 5% (3% for head-of-hollow fills 816.73-b-3)	30 CFR 816.72-e
Vertical distance between terraces of valley fills must not exceed 15 m (50 ft)	30 CFR 816.72-e
Drainage must not be directed over the outslope of a valley fill	30 CFR 816.72-f
The outslope of a valley fill must not exceed 50%	30 CFR 816.72-g
The final configuration of the fill must be suitable for postmining land use	30 CFR 816.71-g

binning both swell and compaction, an average factor of about 1.9 t/m^3 (120 pcf) is a good design density for single-lift truck dumps composed of porphyry or quartzite. Adjustments need to be made for uncommonly heavy material such as iron ore or unusually light material such as borax. The density should also be reduced for conveyor placement or increased for compacted lifts relative to end-dumping by truck.

Single-lift dump capacity is also a function of the angle of repose for the material. For most waste materials this angle ranges between 34 and 40°. Use of 37° is appropriate for volume estimates, but 34° should be used for estimating toe positions.

Hydrologic Considerations

Proper dump design requires a knowledge of existing drainage patterns that will be impacted by construction of a waste dump. A waste dump may interfere with these patterns by impeding flow from the upslope natural watershed or restricting the flow of springs and seeps which may be covered by the embankment.

Dump design must allow safe handling of the anticipated precipitation event specified by the regulatory authority. This design process requires establishing the following site conditions (Vandre, 1980): (1) area of watershed upstream from the embankment; (2) steepness of the slopes, soil type, vegetation cover, and infiltration rates for both natural and

embankment areas; (3) runoff amounts and time distribution for the design event; (4) volume of runoff for the design event if runoff is to be impounded; and (5) peak flow if runoff is to be diverted. The foregoing reference also provides accepted procedures for using this information for surface water control. Consideration should also be given to the possible effect of surface runoff on the ground-water regime (Nelson and McWhorter, 1985; Whiting, 1985). Temporary impoundment can create excess pore pressure within the waste dump or within natural slopes downhill from diversion structures.

In addition to surface runoff, embankment stability can be adversely affected by burying springs or seeps. If it becomes necessary to cover such features, the location and seasonal flow rate should be established. This information will allow design of adequate underdrains if the fill material is not free draining (Cedegren, 1985).

Geotechnical Considerations

A well-designed geotechnical investigation provides necessary geological information and engineering properties of foundation and fill materials. The investigation should identify all factors affecting stability including significant topographic features, soil horizons and depths, rock types, depth of weathering, rock structure, alteration products, accumulation of organic material, and depth to ground water. Samples of soil and rock should be acquired for conventional laboratory testing and in situ field testing when appropriate. Standard techniques include surface geologic mapping and test pits for shallow reconnaissance and drill holes and geophysical surveys for deeper investigations (Welsh, 1985). Geologic maps should identify distribution of soil and rock types on a topographic base map. This map should also identify significant bedrock structural features such as bedding direction, faults, and fracture orientation. Surface features such as soil creep, landslide debris, and springs should be located.

Test pits, which can be excavated by hand, backhoe, or dozer, provide an excellent means of measuring depth of various soil horizons and extent of bedrock weathering. Such excavations provide access for removing samples for laboratory testing or field testing and direct observation of near-surface ground-water conditions. Test pits are usually limited to about 4 m (13 ft) in depth and should be logged immediately after excavation. Prompt attention will reduce the likelihood of premature sloughing, and prompt filling of the pit will help insure safe conditions.

For locations with deep soil accumulations or shallow ground water, drill holes may be required. Normally holes are limited to depths of about 30 m (98 ft), or 3 m (9.8 ft) into bedrock where the soil is relatively shallow. If the entire hole is in soil, auger drilling is usually preferred. When rock is encountered, rotary or core drilling may be necessary. The resulting holes provide the same information as test pits and may be used to subsequently monitor ground-water levels and leachate migration in areas adjacent to the completed waste dump.

Frequently geophysical techniques can be used in conjunction with test borings to determine continuity of subsurface horizons. The most applicable techniques include seismic refraction and resistivity surveys. Both methods can be applied with minimum site preparation and little disturbance to the environment. Proper interpretation of results, however, does require test pits or drill holes to confirm depth to contrasting horizons (Welsh, 1985).

In summary, a well-executed geotechnical investigation

draws upon all existing data for a given site and concentrates on those factors most likely to affect the type of dump to be constructed. When properly planned, the geotechnical investigation provides cost-effective information required for stability analysis of the proposed structure.

STABILITY ANALYSIS

Evaluation of dump stability requires an appreciation of the various modes of failure. These modes include slumping, liquefaction, and foundation failure (Vandre, 1980; Pernichele and Kahle, 1971).

1. *Slumping*—This form of failure is most often confined to the crest area and upper reaches of the inclined surface of end-dumped embankments. End-dumping usually produces a natural segregation of material beginning with the fine fraction near the top and coarser material toward the bottom. Fine material tends to accumulate at a steeper angle than coarse material and periodically sloughs to maintain overall equilibrium. Deep-seated rotational failure is not as common. This form of failure is precipitated by excessive embankment height in cohesive material. Both embankment material and foundation soil can be involved if the soil is of significant depth.

2. *Liquefaction*—The most common form of liquefaction (shallow flow slide) is confined to near surface materials brought to saturation by excessive precipitation or snowmelt. The usual result is a mud or debris flow that can impact downstream areas for a considerable distance. A less common form of liquefaction is referred to as a *blowout*. This type of instability results from retention of water infiltrating from the surface. If sufficient water accumulates and a path is found to the inclined surface of the dump, the saturated debris can move outward allowing the crest to collapse.

3. *Foundation Failure*—Foundation failure can result from base translation or foundation spreading. Base translation most often occurs on steep slopes that are covered with a thin layer of cohesive soil or decaying organic material. Movement is characterized by translation of the entire embankment, or substantial portion of it, along the dump/soil interface. Foundation spreading is characterized by downhill translation of a portion of the toe of the embankment and subsequent squeezing of the foundation soil ahead of the toe. This form of instability is characteristic of rapidly advancing end-dumped embankments over saturated foundation soils. The rate of failure can be rapid with substantial impact to the crest and downslope areas.

A number of mathematical procedures are available for estimating the safety factor for proposed or existing waste dumps. Vandre (1980) presents a series of chart and table solutions covering most forms of failure. These charts are particularly useful for investigating safety factor sensitivity to assumed design parameters and material properties. More rigorous general solutions are available (Bishop, 1955; Morgenstern and Price, 1965; Janbu, 1973; Caldwell and Moss, 1985). Basic principles, assumptions, and differences among these various methods are discussed by Wright (1985).

The reader who wishes to pursue a detailed study of the various "accepted" analytical procedures will find that all methods generally will not yield the same safety factor for a given embankment. Experience and judgment, therefore, must play an important part in selecting suitable methods and input parameters. Vandre (1980) suggests the following factors in selecting appropriate analytical techniques: (1) consequence of instability, (2) confidence in investigation procedures and values for material properties, (3) reliability of design assumptions, (4) ability to predict adverse condi-

tions, (5) control over construction practices, and (6) judgment based on past experience.

DUMP CONSTRUCTION

Specific construction practices are identified in the regulations for excess spoil dumps associated with coal. Little information, however, is available for waste embankments constructed by end-dumping in single lifts. The following list is presented to help identify major considerations in construction and operation of such structures (Bohnet, 1985):

1) New dumps established on steep hill sides are often subject to excessive settlement. The extent of settlement can be minimized by limiting the rate of growth by phasing in the new area gradually.

2) Side-hill fills should be initiated by a pioneer road cut along a contour slightly lower than the anticipated crest elevation. This road will provide a reference for maintaining proper elevation of the dump surface. The road may also provide a platform for light plants and drainage diversion.

3) The surface of the dump should be constructed with a 1 or 2% uphill grade toward the berm. This slope will provide adequate drainage and additional safety for trucks backing toward the berm. Maintaining this grade requires constant resurfacing of the dump to counteract settlement, which can amount to more than 0.3 m (1 ft) per day.

4) The width of the maintained surface of the dump should accommodate the turning radius of the trucks using the dump. For large vehicles, widths of 100 m (328 ft) are adequate with 30 m (98 ft) of crest for each vehicle assigned to the dump.

5) If the dump is to be reclaimed at a slope significantly less than the angle of repose, consideration should be given to benching the operating dump to limit the amount of dozer work required to produce the final slope.

6) The berm should be maintained at one-half of the diameter of the truck tire.

7) Light plants should be high enough to prevent blinding of drivers as they pull away from the berm at night.

8) Trucks that need assistance in dumping large boulders should not be permitted to dump directly over the berm. End-dumping under such conditions could cause the truck to tip over.

9) Stability of side-hill fills may be improved by establishing the operating crest perpendicular to the topographic contours and dumping in a direction roughly parallel to the contours (Campbell, 1985).

MONITORING

Once design decisions are made and construction begins, it is prudent to monitor the performance of waste dumps (McCarter, 1985). Monitoring through the use of instrumentation can improve reliability of performance data and help insure safe working conditions. Applicable instrumentation includes:

Conventional surveying—Nearly all mines have access to theodolites, levels, and EDM equipment. Such equipment provides an expedient way of measuring vertical settlement and total displacement of stations established on the surface of a dump. Adequate coverage, however, requires frequent measurements to establish short-term trends which are important in detecting impending instability.

Extensometers—This term is applied to any one of several devices that permit measuring the change in distance between two points. The two points may be located on the surface (Ko and McCarter, 1975) or below the surface in drill holes

or buried pipes. Extensometers can be positioned so as to measure extension parallel to the surface or compaction in the vertical direction. Data may be collected on an intermittent basis or linked to recording devices to provide a continuous plot of movement as a function of time. In addition, extensometers can be automatically interrogated by a telemetry system or serve to activate warning devices when a preset rate of movement is exceeded.

Piezometers—Devices that are designed to measure pressure acting through the liquid phase in a saturated geologic material are referred to as piezometers. An open vertical hole that permits measurement of depth to standing water is perhaps the most common form of piezometer. An improvement over this observation well is provided by lowering a casing with a porous tip to a given depth in the hole. The casing serves to support the hole and provide a guide for sounding devices used to measure the water level. Multiple casings can also be installed in the same hole and isolated from each other by suitable packing materials (D'Applonia, 1977?). This procedure allows monitoring of pressures at various depths.

Observation wells are not suitable under all conditions. Special application may require more sophisticated electrical or pneumatic piezometers (McCarter, 1985). These devices provide an analog output proportional to the pressure at a specific point.

Piezometers can provide valuable information but they are usually difficult to maintain. Internal shear zones and high rates of compaction can crush or distort the casing or sever electrical or pneumatic lines. These problems are particularly common in deep holes. Shallow holes, on the other hand, generally are easier to maintain and can be used to probe for perched water which may contribute to blowout failures.

Inclinometers—Devices that sense a change in attitude with respect to the pull of gravity are commonly referred to as inclinometers. Inclinometers are usually placed in vertical holes and serve to measure deflection of the hole as differential movement occurs. Special adaptations allow inclinometers to be placed in inclined or horizontal holes (Anon., 1982).

Acoustic Emissions—Stressed geologic material, including fill, provides microseismic events that can be measured by suitable instrumentation (Leird, 1981). The number of events per unit of time appears to be correlated with the magnitude of stress and/or movement. This technique offers promise for dump monitoring, but at this time has not been widely applied. The technology is certainly available, but additional research is needed on proper application and interpretation of data.

Instrumentation provides a convenient way of quantifying observations and allowing automatic collection of data. The importance of on-site, personal inspections should not, however, be overshadowed by the desire for technological sophistication. Experienced equipment operators, supervisory personnel, and field technicians often provide the most important source of information pertaining to the stability and performance of a waste dump. Sufficient care and attention should be given to establishing a mechanism for communicating observations to the individual responsible for operation of the dump. The following list provides a few gross manifestations of potential instability of end-dumped embankments: (1) difficulty in maintaining the berm or positive grade at the crest, (2) shallow steplike fractures near the crest, (3) a change in condensate patterns issuing from the surface in cold weather, (4) a sudden change in turbidity of discharge

water, (5) convex upward curvature of the inclined surface of the dump, and (6) popping noise near the toe.

RECLAMATION

Reclamation of waste dumps involves shaping to acceptable configurations, applying of topsoil or appropriate soil conditioners, planting suitable vegetation, and ensuring successful growth for the required postmining period. The objective is to return the land to a condition as close as possible to the premining state or at least to leave the site in a condition compatible with the surrounding terrain. According to Richardson (1985), the major factors influencing the success of reclamation include: (1) climate; (2) chemical, hydrologic, and physical conditions of the fill material; (3) availability of suitable plant species; and (4) proper management of reclaimed sites.

The amount of precipitation, frequency, and the form (rain or snow) are obviously important factors in establishing and perpetuating vegetation. In addition, the amount of sunlight, temperature, and the number of freeze/thaw cycles significantly affect the length of the growing season and the water infiltration and retention characteristics for a given site.

The nature of the spoil and orientation of the embankment can also have a dramatic impact on revegetation efforts. South-facing slopes receive more direct sunlight and reach higher surface temperatures than north-facing slopes. Soil color influences surface temperatures, which can have an important impact on establishing initial growth. Physical characteristics, such as topsoil thickness, texture, particle size distribution, hardness, retention capacity, and hydrologic conductivity influence biologic suitability and should be determined by laboratory testing before planning reclamation efforts. Laboratory testing should also include determination of salinity; pH; nitrogen, phosphorous, and potassium content; and other chemical properties that will govern the productivity of the site.

Selection of appropriate species is critical to successful revegetation. The proper mix of grasses, shrubs, and forbs helps insure rapid coverage and establishment of environmental equilibrium. In addition, availability of seed and need for bare root or container-grown plants must be anticipated in order to minimize cost and time for completion of reclamation efforts.

Finally, proper management of the reclaimed land is essential. Careful control must be exercised over domestic livestock, and occasionally, native animal life must be excluded from the area until a stable ecology is established.

Reclamation of waste dumps requires application of known agronomic methods coupled with an appreciation of the special problems peculiar to specific mineral resources. Substantial research has been done in the field and detailed information is available (Richardson, 1985).

CONCLUSION

Waste management is an integral part of surface mine planning. Application of existing technology and careful engineering is necessary for economic optimization, safety, and long-term reclamation of mine waste dumps.

6.10 Materials Handling

A.T. YU

SURFACE MINING LOADOUT SYSTEMS

It has been stated that once geology is set and rock is fractured, mining becomes essentially a materials handling proposition. In fact, a recent survey indicated ore and waste handling account for nearly 45% of total mining costs (Michaelson, 1974). The key to the success of a mining venture from that point on depends largely on how efficiently and economically one can move the materials.

Traditional Systems vs. Belt Systems

Over decades, ore or stripping has been loaded by cyclic machines such as shovels, front-end loaders, and draglines onto trucks or rail cars. As pit size and bench height increased, machines got bigger.

The traditional mode of operation is flexible, particularly where selective mining is required and equipment may be readily moved to desired locations as mining plans change. Breakdown of individual pieces of equipment is remedied by the rapid dispatch of spare units. Electrification of shovels and trucks greatly reduced mechanical wear and downtime with resultant significant increases in reliability. Recent introduction of hydraulic machines further improved equipment availability.

Continued escalation of labor costs coupled with the world energy debacle provided the impetus for the introduction and advances of *continuous* belt mining systems. If a belt system is properly applied, it can replace a fleet of trucks with only a few flights of belt conveyors and exchange similarly scores of drivers with one or two operators. Equally dramatic savings are evident in maintenance and repair as well as fuel.

A belt system is fed by a bucket wheel type loading machine if hard rock is not a problem, or traditional shovel and loader operation used in conjunction with in-pit crushing. Discharge of stripping is generally accomplished by a shiftable belt system, coupled with a crawler-mounted stacker (see the section on "Subsystems and Hardware, Belt Modules").

Storage/Reclaim Systems

To ensure continuous operation at the mine and uninterrupted loadout haulage, a *surge facility*, or a storage/reclaim system is required. These systems may be open or housed.

Open storage is cost effective. On the other hand, shelters may need to be built over the stockpiles, in some instances, to keep out weather and to contain dusting. Alternatively, large bins or silos may be used.

Stockpiling is generally accomplished by stackers (rail- or tire-mounted) or overhead devices such as trippers or shuttle belts. Stored material may be reclaimed by gravity underground or a wide variety of machines such as bucket wheel reclaimers, scrapers, or front-end loaders. Sizes of stockpiles can vary from a few thousand to several million tons, whereas bins or silos can be as big as 9 to 18 kt (10,000 to 20,000 st) [silos up to 90 kt (100,000 st) capacity have been planned in Japan].

Geotechnical consideration is often a major factor in the development, design, and management of an open storage/reclaim system. Poor soil can bring about ground failures

that result in major losses of ore or concentrates as well as equipment. Where an alternate site is not available, relieve platforms supported on drilled piers can be a solution. Another approach is to build a berm around the stockpile to provide a counteracting stabilizing force. This is often accomplished by close monitoring with instrumentation coupled with a programmed stockpile reclaim strategy over a period of time until the soils are stabilized (Yu, 1982).

Large lumps or sticky material with clayish content impede steady flow and create a problem in reclaim operation. When reclaiming stockpiles by gravity, traveling plow feeders over a slotted tunnel roof have done wonders in promoting positive flow (Fig. 1). To ensure free flow, bins and silos should be designed with a *mass flow* principle. Otherwise, bin bottom activators such as a Vibrascrew type of pneumatic device should be used. In very difficult situations, pneumatic cannons may be installed at strategic locations to dislodge wedged-in material.

Conceptually a storage/reclaim system may be viewed as a necessary evil. Ore or concentrates in storage adds to inventory costs, requires double handling, occupies valuable space, and creates environmental problems, particularly in open storage. Consequently, meticulous fine-tuning is required to minimize the added cost. In this effort, one must recognize the fundamentally conflicting desires of engineers, operators, and owners. For example, the owner is primarily concerned with profit whereas the engineer may overemphasize state-of-the-art technology or overdesign the system for a limited throughput. The operator is inclined to add redundancy, larger-than-necessary storage, and easy maintenance at any cost.

Effective fine-tuning requires careful consideration of the needs and desires of all three parties concerned to optimize the system overall. The engineer must not overlook the operator. Both the owners and operators must keep abreast of developing new systems, their multitude of variations as well as their cost implications (Yu, 1982).

Mine and Plant Haulage Systems

Four principal haulage systems serve a mining operation: truck, rail, aerial tramway, and belt. Owing to their significant cost impact, numerous new systems are continuously being developed by manufacturers and the US Bureau of Mines.

By far the most commonly used piece of equipment in a mining operation is the haul truck. A truck can get into the most difficult area in a mine and it is generally regarded as having the greatest flexibility. Based on how the cargo is discharged, trucks are divided into side-dump, bottom-dump, and rear-dump types. For long distance haulage, the loads may be distributed into two separate carriers thus creating a truck-trailer configuration.

To attain the economies of scale, in the 1960s, payload capacities of haul trucks grew from 59 to 90 t (65 to 100 st). The introduction of electric drives increased reliability and reduced maintenance. The 1970s saw the development of the 154-t (170-st) diesel electric trucks. Over 1400 of these units were built in the 1970s, and are currently in use virtually everywhere in the world. Trucks over 272 t (300 st) in capacity are currently in active development for the 1980s.

Fig. 1. Traveling rotary plow feeder.

One of the major problems with trucking is the need for a large number of operators. Escalating fuel costs have added yet another problem. To cope with the high fuel costs, a trolley power-assist system has been developed. This system provides commercial electric power through an overhead line to power electric-drive haulage trucks in certain areas in the mine. Up to 75% of fuel savings was indicated in certain test installations.

To reduce labor, the ATC (automatic truck control systems) has been developed. The truck operation is directed from the remote control center. Although this system is now available for simple mining applications, additional development is required to achieve reliability and maneuverability in complex and large open pits (Lyon, 1981).

For high volume haulage over relatively difficult terrain, rail generally is preferred over trucking. The smooth rail tracks substantially reduce rolling friction. The multitude of rail cars in one string provides substantially greater capacity over individual trucks [6350 to 13 608 t (7,000 to over 15,000 st) per train load compared to 90 to 272 t (100 to 300 st) per truck]. Moreover, electrification is readily achievable with a railway operation.

Gradient and horizontal curve limitations make railroads costly to construct over rugged terrain [2% slope and 6° horizontal curve equivalent to a radius of 303 m (995 ft) have been normally regarded as a maximum]. In extreme cases, a 3% slope and a 10° curve equivalent to 175 m (573 ft) radius have been used. Braking under load can also be a safety problem in a downhill operation.

If the tonnage to be carried is not large [272 to 363 t/h (300 to 400 stph)], an aerial tramway could be a preferred choice of haulage in extreme rugged terrain. A bicable system can carry up to 4.5 t (5 st) per car running at 183 m/min (600 fpm) and up to 453.6 t (500 stph) (Anon, 1976). These systems can negotiate as high as a 30° gradient, compared to normally 15° to 18° for belt conveyors, up to 10° for truck roads, and 2° or 3° for rail tracks.

The need for reliable and economic means of haulage has resulted in the increased usage of belt conveyors. When properly designed, a belt conveyor system can traverse rugged terrain, carry substantial tonnage with little manpower and comparatively low power consumption (in a regenerative configuration, it can even generate power), and requires little maintenance (Anon, 1982). Recent development in the shift-

able and extensive variety provides a great deal of flexibility to be applied in many underground and open pit mining operations (see the section on "Subsystems and Hardware, Belt Modules").

Compared to rail or trucks, one of the drawbacks of a belt conveyor system is its inability to carry excessively large lumps. To overcome this problem, in-pit crushers have been used. Today, belt conveyors can be as wide as 306 cm (120 in.), running at well over 305 m/min (1000 fpm), and can carry more than 36 kt/h (40,000 stph). The longest conveyor belt system ever installed was the 100-km (62-mile) system in Morocco carrying phosphates.

Principally responsible for the belt's increased length and capacities is the emergence of the stranded steel cable core. The steel cable core concept was first introduced in Europe. Today, the special brass coating insures strong bonding of the stranded wires to the rubber. The latest cable splicing techniques, when properly applied, enable the joints to have stronger tensile resistance than the cable itself. The allowable working tension of the steel cable core belt ranges from 44.6 kg/mm (2500 lb/in.) of belt width for 6.35 mm ($\frac{1}{4}$ in.) diam cable to 107 kg/mm (6000 lb/in.) for 9.5 mm ($\frac{3}{8}$ in.) diam cable.

A comparison of the advantages and disadvantages of several commonly used haulage systems is shown in Table 1.

Deep cleats made of rubber or metal have been used successfully to surpass the conventional 18° to 20° incline limit. To climb still steeper inclines, devices such as a wheel, a hugger belt, or a looped belt (Yu, 1971) have been successfully used. By banking idlers at key locations, a belt conveyor has been made to traverse a horizontal double S-curve of 610 m (2000 ft) radius. In the open pit mine at Garsdorf, Germany, a conveyor was able to round a horizontal curve of 305 m (1000 ft) radius. In New Caledonia, a single flight conveyor carries nickel ore 11 km (6.8 miles) by following the contour of the mountain, rounding four horizontal curves with a minimum radius of 1050 m (3445 ft) (Fig. 2). See Table 2.

In a conventional belt system, the cargo on the rubber belt is supported transversely on intermediate troughing

idlers and longitudinally by the tension in the belt itself. The belt tension is in turn carried by its fabric carcass or the steel cable cores, as the case may be. To relieve the belt of high tensile stresses and to gain other benefits, the cable belt system was developed whereby the cargo on the belt is carried on the two supporting cables via transverse stiffness imbedded in the belt.

The cable belt system was first conceived late in the 1940s. The introduction of replaceable polyurethane-lined sheaves has been responsible for its recent success. Latest data indicate rope life varying from 18 months to 6 years. This system has scored success in long distance haulage of coal. An installation for crushed coal in West Virginia runs nearly 21 km (13 miles) with single flight length of 15 km (9.3 miles). In Australia two single flights of 30.4 km (18.9 miles) and 20 km (12.4 miles), have been used for bauxite (Anon, 1982).

The first cable belt application in a metal mining operation was built in 1976 in Arizona. It moves copper ore from Asarco's Mission Point 10 km (6.2 miles) to Anamax's Twin Buttes concentrator. The belt is 1067 mm (42 in.) wide, runs at 244 m/min (800 fpm) to handle 1814 t/h (2000 stph). The single flight negotiates a 60° bend at about 0.8 km (0.5 miles) from the primary crusher feed end. It has operated successfully in delivering its rated 4.5 Mt/a (5 million stpy) (see the case history on Twin Buttes).

Economics of each of the haulage systems is quite situation-dependent, particularly since operating costs over the life of the system can significantly overshadow the capital costs. Given the unpredictability of fuel cost fluctuations, haulage system economics must be analyzed on a case-by-case basis and updated by the changing worldwide and local economic scenarios. Rule of thumb estimates can be quite misleading.

One approach is to tabulate costs and cash flow analysis for each alternative considered over its entire service life. This would encompass the investment, fixed costs such as taxes and insurance, as well as operating costs. These numbers are then *present-valued* with an assumed rate to provide a total net present value of each of these alternatives.

A recent study (Benavides and Schuster, 1982) compares

Table 1. Comparison of Commonly Used Haulage Systems

Haulage System	Advantages	Disadvantages
Railroad	Rugged equipment-resistance to abuse Same installation may be used to haul equipment, supplies, and personnel No need for power transmission or large power plant if diesel equipment is used	High construction costs, especially in rugged terrain Inability to negotiate steep grades, consequently requiring much longer run Maintenance High accident rate in difficult terrain
Trucks	Low investment cost Highest flexibility Can carry equipment, supplies, and personnel	High maintenance, road, and equipment Require a team of operators and shop personnel High operating and fuel costs High accident rate
Belt conveyors	Low operating cost Comparatively lower investment cost for high tonnage and rugged terrain Requires least number of operators Reliability Low noise level	Normally cannot be used for hauling supplies, equipment, or personnel Rubber belt is vulnerable to damage unless all design precautions are exercised and operating restrictions are properly policed
Tramway	Ability to negotiate rugged terrain Environmentally favorable	Low capacity Relatively high maintenance

three modes of haulage from four mines to a processing plant with distances varying from 1.6 to 8.9 km (1 to 5.5 miles). Using a 10% inflation rate and 15% discount rate, the study concluded for this particular situation as follows:

	Present Value (in \$ million)
X (belts)	58.25
Y (rail/truck combination)	71.40
Z (trucks)	160.64

The construction cost of the 8.8-km (5.47-mile) belt was estimated to be \$1771/m (\$540 per ft). A comparable tramway system could cost \$600 to \$2000/m (\$200 to 600 per ft) (Bonasso, 1983). For estimating purposes, recent experience indicates four to seven units per ton-mile. In downhill regenerative systems, energy savings could cause it to decrease to as much as 2¢ per ton-mile.

SUBSYSTEMS AND HARDWARE

Belt Modules

In contrast to a permanently fixed installation, a modularized belt is made up of readily dismantled unitized components, mounted on skids, rail ties, wheels, or crawlers (Fig. 3). Each of the components, including the intermediate, tail, head, and drive sections, may be steered easily and moved around to fit virtually any mode of operation dictated by the needs of an open pit operator, according to a wide variety of mining plans, and in conjunction with an assortment of excavating and haulage equipment.

Tire-mounted short portable conveyors have been around stockpiles for decades. Skid or tire-mounted dozer traps are quite versatile in cleanup in the pit when used with dozers, loaders, and trucks.

Among the virtually limitless varieties of belt modules, by far the most widely used and successfully applied in surface mining is the *shiftable* belt (Fig. 4). When conditions are right, a *shiftable* belt as long as 2286 m (7500 ft) can follow the advance of the mine face with a crawler-mounted, bucket-wheel excavator, to yield an economic ton of moved earth. The intermediate sections of these belts are generally supported on rail ties with special connections to permit lateral shifting without damage to the supporting structure (Fig. 5). A pair of rails is generally required to support a tripper for discharge of muck on the main belt at any intermediate point, or a traveling hopper to receive the feed to the belt. These rails are fastened to the ties with specially designed fittings (known as *Nebelung* sole plates) to allow

for relative motion between the rail and the ties during shifting. These rails also serve as a point of anchor for the rollers located at the end of the dozer-mounted shifting arm. The tail and head sections of the shiftable belts may be on skids, crawlers, or temporary concrete footings, depending on the relative permanency of the installation.

Typically, ore or waste is loaded through the discharge conveyor boom of a crawler-mounted, bucket-wheel excavator directly onto the shiftable belt. To add greater flexibility and reach, an intermediate crawler-mounted transfer belt (generally known as a *bandwagon*) may be used. Shovels, trucks, or scrapers have also been used to feed a shiftable system, though usually not directly. If large boulders are beyond the carrying capacity of the belt, a scalping screen or a grizzly may be required in the circuit. Wherever feasible, in-pit crushing may be considered to result in a more economic belt system by virtue of a narrower belt width.

Meanwhile, stripped overburden from a pit may be fed by scrapers or trucks in the pit onto a stationary belt. In turn, the latter is fed onto a shiftable belt through an extensible conveyor. The shiftable belt, initially built on a high ramp, advances toward a large valley eventually to be filled by the mine waste.

Generally, discharge from the shiftable belt is by way of a crawler-mounted boom stacker (Fig. 6). A track-mounted tripper serves as the transfer from the shiftable belt to the stacker. The stacker traverses along the long belt and, to the extent of the reach of its boom conveyor, fills the valley with strippings brought out from the mine over the shiftable system. The reach of the stacker boom is the extreme operable limit of a shiftable belt in the position where it has been shifted. Once this limit is reached, the stacker has nowhere to dump additional material; therefore, the ground has to be leveled and the belt shifted further out toward the empty valley. This operation is repeated until the entire valley is filled.

As early as 1890, the horizontal manual rail shifting technique was first introduced in Germany's lignite fields to enable the rail car tracks to follow the advance of the mine face (Goergen and Ambatiello, 1968). Shifting of modularized belt conveyors began in 1931. Shifting by machine, however, did not come on the scene until 1951, when the Bavarian Lignite Co. (Bayerischen Braunkohlen-Industrie, A.G.) tested what was probably the world's first shiftable belt conveyor in Schwandorf. The belt was 1016 mm (40 in.) wide and 518 m (1700 ft) long. In shifting it was pivoted horizontally with one end held and the far end swung around a distance of 25 m (82 ft). The entire operation was completed in 8 hr.

Fig. 4. Twin Buttes waste dump area when shiftable system began its operation, circa 1968.

The pioneer modules were mounted on a grillage of rails without rigid connections between longitudinal modules. A set of rails had to be laid alongside the belt to support the track-mounted shifting machine in Schwandorf. This was cumbersome and slow. Little wonder it soon gave way to the far more flexible *trackless* shifting system, featuring specially built shifting heads mounted on crawlers. The tripper rails on the belt modules were to be lifted slightly and dragged toward the shifting machine as the latter traversed forward, parallel to the new centerline of the belt. Though a great deal more sophistication and refinement have been introduced into today's shiftable belt modules, their fundamental concept and configuration has not departed materially from the forerunner of the early 1950s.

Outside Germany, Nchanga Consolidated Copper in Zambia's rich Copperbelt was probably one of the first users of the shiftable system (Anon, 1960). Search for an efficient and economic method to remove the large amount of lateritic overburden [projected at 9:1 waste-to-ore ratio at 244 m (800 ft) in depth] led to the bucket wheel and shiftable belt system. Commissioned in November 1958, the system features boom-mounted bucket wheel excavators on crawlers. Working with them are some 4267 m (14,000 ft) of belt

conveyors consisting of shiftables at the mine bench and the dump as well as transfer belts in between. The shiftable bench belts follow the advance of the mine face whereas the dump belt feeds a crawler-mounted stacker (Fig. 7).

Overland transfer belt *F* is ramped up to 21 m (70 ft) above grade to feed the extensible conveyor *G*, which may be extended as the valley is being filled. Conveyor *G* feeds the 914-m (3000-ft) long shiftable belt *H* built initially on a 21-m (70-ft) high levee. The crawler-mounted dump stacker has a 76.2-m (250-ft) boom conveyor. The valley is capable of receiving 76.5 million m³ (100 million cu yd) of overburden.

Unlike the German lignite operation, where belt shifting is relatively infrequent, Nchanga's bench belts often have had to be shifted, shortened, or lengthened at three- to four-week intervals. Further, to minimize stripping and simultaneously to maximize ore exposure, the bench belts must be constantly shifted to follow the dip of the ore body. To accomplish this, three extensible shiftable bench belts are required.

The Nchanga belts are 1219 mm (48 in.) wide, each running at 244 m/min (800 fpm) to yield a maximum rate of 3 266 t/h (3600 stph). Each of the steel stringer modules

Fig. 5. A shiftable conveyor several thousand meters (feet) long can be shifted laterally into new positions by a special rig mounted on a bulldozer.

Fig. 6. Crawler-mounted boom stacker.

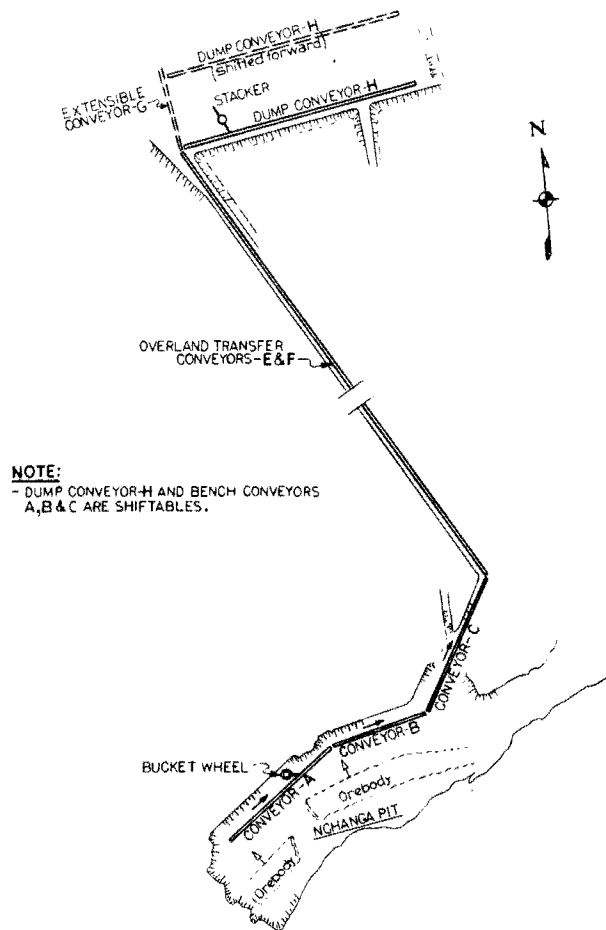

Fig. 7. Schematic diagram of the shiftable and extensible belt system at Nchanga pit.

carries 762-mm (30-in.) troughing idlers spaced at 1 m (3 ft 4 in.). The intermediate posts are mounted on 254 × 152 mm (10 in. × 6 in.) timber ties and the drive sections on skids. With the help of a D8 dozer equipped with a special roller arm, in 0.6 m (2 ft) bites, a 670.6-m (2200-ft) belt may be shifted a distance of 39.6 m (130 ft) in a matter of four 12-hr days. Moving an entire conveyor between benches, however, would normally take somewhere between two to three weeks.

Since Nchanga, the use of the shiftable belt has begun to spread. Some of the better known examples are the 3.2 Mt/a (3.5 million stpy) Neyveli lignite operation in Madras, India; the Kursk magnetite mine in the USSR (Gartner, 1966); the Oroville Dam project in the US (Anon, 1966); the backfill project in Singapore (Von Campenhausen, 1967); the Washington Irrigation's Centralia coal project in the state of Washington; the Guyana Bauxite Co.'s mines in McKenzie; the Twin Buttes Copper operation in the US (see the case history on Twin Buttes); the Opencast Mine Most in Czechoslovakia; and Goonyella mine for coal in Australia.

A wealth of knowhow and operating experience in the shiftable belt modules has been amassed over the past three decades. Significant advances have been made in the methodology and hardware to make it a versatile and virtually foolproof system. The 3- or 5-roll Garland idler, having its individual rolls linked together by ball joints, provides greater impact resistance, promotes centering of the load, improves

alignment of the belt, and has the advantages of ease of installation and maintenance. Troughing angles have been increased to 45° and, in the case of 5-roll Garlands, to as much as 60°. V-type return idlers further help belt alignment.

In-Pit Crushing

DENNIS K. MORTENSEN

The major sources of all hard rock tonnages mined today come from either quarries or open pits. Ore is normally fractured within the pit by blasting and then truck-hauled to the pit rim for further crushing and transporting to the concentrator. Waste encountered in the mining process is generally truck-hauled out of the pit to designated dump areas. Cost estimates for this type of truck-haulage system range from 25% to 50% of the total mining costs of a typical open pit mining operation (McQuiston and Shoemaker, 1978). Fuel, lubricants, tire replacements, and operator's wages account for more than 80% of the cost of truck haulage and these costs probably will continue to increase at a steady rate (Kok, 1980).

Mining companies are continually looking for new ways to reduce these costs. Equipment replacement with larger units, as well as converting to conveyor haulage out of the pit, offer possibilities for lowering the cost per ton of material handled. The installation of belt conveyors as close to the mining face as possible would appear to be the logical solution to the cost problem. This would allow for maximum use of belt conveyors, which are much less labor-intensive and more energy-efficient than trucking systems. The fallacy of this solution to the problem is the impracticality of direct loading mine-run material onto a belt conveyor, mainly due to the material's excessive lump size. Some means of reducing the lump size to that which a belt conveying system can handle efficiently is necessary. An in-pit crusher, either fixed or portable and used in conjunction with a belt conveyor system, can offer one of the most effective available methods of reducing energy consumption and mining costs.

Although the potential for cost savings with in-pit crushing/conveying systems is recognized, many mining companies have considered implementing such systems, but few have done so. The need to mine both ore and waste at the same time makes it impractical to place crushing/conveying systems at each working face. It is therefore necessary to be able to use trucks to transport all material of the same classification to some convenient point from which it may be crushed and conveyed from the pit.

Many mines are required to simultaneously mine ore, leach rock, and waste. Such a mining operation would require the flexibility of truck haulage to change either rock type or destination at a moment's notice. Some mining companies have combined the flexibility of truck haulage systems with fixed in-pit crushing/conveying systems. In southern Arizona both the Anamax Mining Co. operation and the Duval Sierrita operation have done so.

At the Duval Sierrita* operation two fixed 1520 × 2260 mm (60 × 89 in.) gyratory crushers have been installed in the pit to crush ore (Fig. 8). The ore is conveyed out of the pit and transferred to a 1.37-m (54-in.) overland conveyor that extends to the concentrator. Duval's two original crushers, installed near the pit rim, were converted to handle waste by adding a waste conveying and stacking system. Table 3 shows the original operating components of Duval's system.

Metric equivalents: in. \times 25.4 = mm; ft \times 0.3048 = m; st \times 0.907 184 7 = t.

At the Anamax Mining Co. operation, two fixed 1370×2030 mm (54×80 in.) gyratory crushers were installed in the pit and were able to crush either sulfide ore, oxide ore, or waste followed by conveying to the pit rim (Fig. 9). A transfer system at the pit rim could route sulfide ore, oxide ore, or waste to its final destination by 1.52-m (60-in.) conveying systems designed to handle each class of material. As the pit was deepened, an additional waste handling system was installed. The system consisted of an in-pit crusher and conveying and stacking system similar to the installation at Duval. Table 4 shows the original operating components of Anamax's system.

With regard to both waste and ore handling, the question of where to crush becomes very important from the standpoint of permanence and convenience. The crushing/conveying system should, ideally, be positioned so as to minimize any inconvenience it may create with regard to the future expansion of the mining operation. A location convenient to pit working faces, but not shielding ore that would otherwise be mined, is desirable. However, rarely is either a pit wall or an in-pit crushing/conveying system allowed to remain with any degree of permanency.

Semimobile crusher/conveyor installations address both questions of permanence and convenience and may be a better solution to the problem. These systems can be built as several subunits and placed in the main working area of the pit. Haulage distances to the crusher can be kept short and the

system can be moved once the haulage distances become too long. Either minimal or no foundations are required for the equipment, thus resulting in a further cost savings. The systems can be designed so that each of the subunits, e.g., apron-type feed conveyor or crusher, can be transported as a single unit to its next location.

Past development of mobile primary crushers has centered mainly in Germany where soft iron ore and limestone deposits are readily accessible and adaptable to movable systems. Impact type crushers with large feed openings resulted in large reduction ratios but generally suffered from low capacities. Single-toggle jaw crushers and short-shaft gyratories were also used until manufacturers responded with larger crushers, feeders, and movable supports. Today mobile crushers have capacities of up to 3630 t/h (4000 stph).

One of the first large capacity, readily portable units suitable for large shovel operations was built in Mexico in 1975. An Allis-Chalmers 1370×1880 mm (54×74 in.) gyratory crusher, incorporated in a Weserhütte design, was fed by a 24.6 m long by 2.2 m wide (81 ft by 87 in.) apron feeder sloped at a 25° angle. The unit, operating in a limestone deposit, was fed by front-end loaders and originally operated one shift per day, six days per week. The unit was moved by three hydraulically operated feet, which walked at a speed of 0.02 m/s (4 fpm). The normal operating tonnage for the unit, which was equipped with a Hydrosset unit for adjusting the crusher setting, was 680 t/h (750 stph). As of late 1982,

the crusher was still operating as a portable crusher. The crusher has been moved an average of once every two years since 1975.

The US Bureau of Mines (USBM), in conjunction with the Fuller Co. and Gard, Inc., previously concluded a study to establish "... the current and projected requirements and the technology of movable in-pit primary crushers to be used in hard rock surface mines." (Johnson, et al., 1981). During the course of the study, a survey of 11 operating mines was made to determine which characteristics of a crushing system

were most desired by mine personnel. Table 5 shows the results of that survey. All of the mine personnel surveyed were interested in portable crushers. The gyratory-type primary crusher was preferred due to its reliability, durability, and relative freedom from clogging. Crushers with large capacity were also preferred so as to minimize the number of crushers and conveyors required. A maximum frequency of one move per year was envisioned by some operators while others preferred a system to remain unmoved for five years or more.

Table 4. Anamax Mining Co. Twin Buttes Mine

Ore type	Copper-porphyry skarn, 2371 kg/m ³ (148 lb per cu ft)
Concentrator capacity	40 kt/d (44,000 stpd)
Shovel size	11.5 m ³ (15 cu yd)
Truck sizes	90 and 154 t (100 and 170 st)
Primary crushers, original	Two 1370 x 2030 mm (54 x 80 in.) gyratories
Capacity of dump pocket	55.8 m ³ (73 cu yd)
Crusher feeder	Hewitt-Robbins Eliptex 2-E-13 vibrating grizzly
Length and width of grizzly section	7.24 x 2.44 m (284 x 96 in.)
Slope	6°
Spacing bars	Approximately 254 mm (10 in.)
Estimated % ore through grizzly	65%
Method of breaking or removing oversize	Rock grapple
Open-side setting (product size)	216 mm (8½ in.)
Crusher drive	Vee belt
Capacity of crushed ore pocket	Approximately 38.2 m ³ (50 cu yd)
Crushed ore feeder	Eliptex E-13 vibratory, material movement approximately 18 m/min (60 fpm)
Takaway belt	1.52 m at 203 m/min (60 in. at 667 fpm)
Service crane	Mobile
Coarse ore stockpile (after crusher)	60 800 t (67,000 st) live, after secondary

Source: McQuiston and Shoemaker, 1978.

Based on the USBM survey and general crusher principles, the following design criteria have been recommended for in-pit movable crushers:

- 1) The crusher should be able to reduce all run-of-mine material normally received.
- 2) The crushed product should be at the desired size for conveying.
- 3) The crusher should produce the desired throughput.
- 4) The system should be readily relocatable.
- 5) Operating costs should be comparable to a fixed installation.
- 6) The crushing/conveying system should be labor efficient.
- 7) Component wear life should be designed at a maximum.
- 8) An operating availability of not less than 85% should be designed into the crusher.
- 9) Maintenance should be rapid with efficient parts availability.
- 10) Site preparation should be minimized.

Currently, most portable in-pit crushing systems are finding use in the lower tonnage quarry stone industry.

Dutec, a division of Duval Corp., introduced a semiportable crushing system designed to reduce operating costs by incorporating the generally accepted design criteria for movable crushers (Anon, 1982). The equipment was assembled at the company's Sierrita operation in southern Arizona for start-up in 1982. The three-section system consisted of a semiportable feeder, crusher, and discharge conveyor. The subunits were designed so that each section could be moved with a crawler-type transporter up a maximum grade of 12% at a speed of 0.22 m/s (0.5 mph). The 895-kW (1200-hp) diesel-powered transporter had a lifting capacity of 1089 t (1200 st), 20% greater than needed to move the heaviest section. It was anticipated that the entire three-unit system could be moved a distance of 0.805 km (0.5 mile) in the pit to a newly prepared site and be ready to run in a 48-hr period. The new equipment was probably the largest crusher-feeder system in the world, as well as the first use of a semiportable gyratory crusher in an open pit copper mine. The crushing unit, a 1520×2260 mm (60×89 in.) gyratory, had a throughput capacity of 3630 t/h (4000 stph) and all units were serviced by a 360-t (400-st) maximum capacity rough terrain crane.

In open pit mining, the replacement of fixed crushers and truck haulage with semimobile crushers and conveyor haulage can result in an effective means of reducing both energy consumption and constantly mounting mining costs.

The systems now available or in the planning stages offer savings that appear to be readily achievable. However, each situation must be studied on its own merits since no two cases are sufficiently similar to permit a blanket statement of policy.

Bucket Wheel Machine

Much of the pioneering work for the wheel-on-boom excavator was done in Germany's brown coal (lignite) industry. This machine features a series of digging buckets along the perimeter of a steel wheel, supported at the head end of a steel boom (Fig. 10). The wheel is positioned at the face of an excavation bank or a stockpile by traversing the machine and moving the boom. As the wheel rotates, the buckets dig up the material and discharge it onto a belt conveyor supported by the boom. The boom is, in turn, supported by an A-frame. The entire machine is usually mounted on crawler tracks for maneuverability. These ma-

chines may also be rail-mounted. The boom is normally raised or lowered by a hoist winch. The boom conveyor conveys the excavated material onto other connecting conveyor systems.

Today the capacities of these machines can vary from 199 to 10 704 m³/h (260 to 14,000 cu yd per hr). In the extreme case, the wheel on the boom can have a vertical range of movement of as much as several hundred meters. The largest wheel has a diameter of nearly 15 m (50 ft). The digging effort can go up to 1019 kg/cm²/cm (14,500 psi per in.) on an individual bucket tooth. These machines have been used successfully to excavate medium to hard digging materials such as coal, gypsum, phosphate rock, chalk, and soft limestone.

The wheel-on-boom excavators are now used worldwide in mining operations, especially for stripping of overburden. Smaller machines are used for stockpiling and reclaiming.

In an open pit operation, typically the height of a bench should be about half the diameter of the wheel. Thus a 16-m (52.5-ft) high face may be excavated in four 4-m (13-ft) benches by an 8-m (26-ft) diam bucket wheel. As the boom-mounted bucket wheel slews through the face, it makes a crescent-shaped cut (Fig. 11). The tangent of the crescent parallels the direction of machine travel. Both ends of the crescent are perpendicular to the direction of travel. The boom slewing speed should be varied as the secant of the boom slew angle from the direction of travel to compensate for the varying depths of the crescent. This increases the width of the cut to obtain a constant bite of depth times width. Cutting the extreme tapered ends of the crescent is inefficient. The depth becomes too shallow and boom slewing must slow, stop, and reverse direction. Consequently, the total slew angle for mobile boom-mounted bucket wheel reclaimers should be limited to about 160°.

Quality Control

Trucks are weighed by platform scales with the weighing mechanism set underground. Reading and recording are generally carried out in a control cab at the ground level. Computerized operation provides automatic waybill printout and weight totalizing. Rail cars are weighed in a similar manner.

Automated and accurate weighing can be accomplished at loading if material is metered into trucks or rail car via weigh hoppers. With the use of a programmable controller, waybills from each car in the long train are automatically printed out as loading proceeds (Yu, 1982).

Mechanical scales for weighing in transit have been in existence since the 1920s. With the emergence of electronic and nuclear scales in the 1950s and 1960s, respectively, there is now a choice of three varieties. Under ideal maintenance conditions, the accuracies of a mechanical or electronic scale can be expected to be within $\frac{1}{4}$ of 1%. Although it has less maximum accuracy, the nuclear scale works on the principle of mass indications and hence has the advantage of being less sensitive to fluctuation of belt tension. Consequently, it may be installed on such locations on a stacker belt where belt tension fluctuates widely and electrical or mechanical scales would not render any reasonable accuracy.

The counterpart of weighing in a quality control subsystem is sampling. The technology and methodology developed for bulk sampling can be quite complex, often involving high-powered statistics as the conceptual foundation. A practical approach, however, has been delineated (Yu, 1972).

As the quantity of raw materials to be handled has increased, so has the need for quality control. Accordingly, long strides have been made in the technique of automatic,

Fig. 10. Close-up of a boom-mounted wheel reclaimer.

mechanical sampling. Substantial progress has also been made in the development of equipment and sampling theories as well as codes and specifications on an international basis (Anon., 1982).

CASE HISTORIES

DENNIS K. MORTENSEN

Twin Buttes (Copper)

The Twin Buttes mine,* located approximately 40 km (25 miles) south of Tucson in the Pima Mining District of

* Twin Buttes is now closed.

southern Arizona, was operated by Anamax Mining Co. (Fig. 12). Anamax Mining Co. was a partnership, formed in 1973, in which 50% interest was held by Atlantic Richfield Co. and its wholly owned subsidiary, Anaconda Arizona, Inc., and 50% was held by Amax Arizona, Inc., a wholly-owned subsidiary of Amax Inc. Mining activity in the district dates back to the 1870s when surface deposits of copper were first commercially mined.

In 1963 The Anaconda Co. entered into a long-term lease agreement with Banner Mining Co. to determine the feasibility of developing an open pit mine at the Twin Buttes site (Knaebel, 1970). Based on Anaconda's exploration data, the decision was made to develop the mine; thus, the largest known preproduction stripping operation in the history of mining began in mid-1965. It linked earthmovers and con-

veyor belts in an unusual approach to the development of a pit that became 2200 m long, 1700 m wide, and 365 m deep (7200 × 5600 × 1200 ft).

In order to reach the ore more than 227 Mt (250 million st) of alluvium and waste rock, at a depth of 152 to 244 m (500 to 800 ft), had to be removed.

Extensive studies to determine the most economical way of handling the material resulted in the decision to install an in-pit conveyor system. The system was operated in conjunction with a massive scraper and truck-shovel operation. The decision by Anaconda was significant to the mining industry since it marked the first installation of a high-capacity, high-tension belt conveyor system in a domestic hard-rock, open-pit mine.

The first material handling system designated *A* and *B* consisted of two 1.52-m (60-in.) wide belt conveyors (Fig. 13) (Almond and Huss, 1982). These conveyors, with a capacity of 7260 t/h (8000 stph), transported the material out of the pit at a 25° slope and overland a total of about 3200 m (2 miles). The material was deposited into a 910-t (1000-st) loadout bin from which it was trucked to tailings pond sites for dam construction.

In 1969, after removing some 150 m (500 ft) of alluvium, waste rock capping was encountered. In anticipation of the waste rock, two individual 1370 × 2030 mm (54 in. × 80 in.) gyratory crushers had been installed in the pit wall,

designed to be fed from end-dump haul trucks (Figs. 14 and 15). Crushed ore or waste from these crushers fed at a rate of 4540 t/h (5000 stph) onto two parallel, 1.52-m (60-in.) belt conveyor systems designated R1-R2 North and R1-R2 South.

A transfer system near the pit rim allowed either of the *R* belts to feed material onto either of three other belt systems. One belt ran to the north and carried only sulfide ore to the secondary crushing plant. Another belt running to the north carried either oxide or sulfide ore to the truck bin. The third belt ran to the south and carried only waste to a dump where the material was distributed by a shiftable belt conveyor equipped with a track-mounted stacker conveyor. In 1968, the capital cost of each crusher installation was estimated at \$1.1 million.

In 1972, the *A* and *B* conveyors, as well as the truck feed bin, were disassembled and reinstalled on the south side of the pit. Labeled *C* and *D*, they were 730 m (2400 ft) and 915 m (3000 ft) long, respectively. Truck bridges were built across the *C* conveyor at various bench elevations and material from bottom-dump haulage trucks was fed through a grizzly-feeder arrangement onto the conveyor. At the end of the *D* belt, bottom-dump trucks reclaimed the material from the truck hopper and hauled it to the waste dump areas.

In 1975, a third 1370 × 2030 mm (54 in. × 80 in.) crusher and conveyor system was installed lower in the pit for waste rock only. The new system also conveyed the crushed rock at a rate of 4540 t/h (5000 stph) to the tail end of the existing *C* conveyor for transport to the dump area. At the same time, the *D* conveyor was extended to feed onto a shiftable belt conveyor, *E1*, also equipped with a track-mounted stacker-conveyor.

Future expansion of the dump area anticipated the *E1* belt to become a fixed installation. A new shiftable belt, *E2*, would be fed by *E1*. The existing stacker-conveyor would be moved to the new *E2* belt for distribution of waste.

By the end of 1982, more than 1.22 Gt (1.34 billion st) of material had been removed from Twin Buttes at a stripping ratio of more than 6.6 to 1.

In 1976, Anamax and Asarco Inc. concluded several years of negotiations and signed the Eisenhower partnership agreement to form Eisenhower Mining Co. The partnership was formed to permit exploitation of Anamax's Palo Verde property and adjacent Asarco holdings as a single mining unit (Brost, 1979). In order to transport Anamax's portion of the ore to the Twin Buttes site, a decision was made to install a conveying system 10.3 km (6.4 mile) long (Fig. 12). The system, again fed by a 1370 × 2030 mm (54 in. × 80 in.) gyratory crusher, was supplied and installed by Cable Belt Ltd. England (Fig. 16). The unique feature of the system was the separation of the driving (tension) medium from the material carrying medium. In the Cable Belt system, the material was carried on a transversely stiffened belt, riding on two endless loops of wire rope that transmit the driving tension. Molded rubber grooves on the belt grip the wire ropes, which are supported at intervals by pulleys (Figs. 17 and 18). The wire ropes were driven by Koepe friction wheels at the drive unit, which incorporated a differential to allow for slight differences in rope movement. Because the ropes supply the driving tension, only enough tension was applied to prevent folding of the belt.

The 1.07-m wide (42-in.) belt was designed to carry 1815 t/h (2000 stph) of copper ore at a speed of 251 m/s (824 fpm). The system was commissioned in early 1979 and by year-end 1982 had transported approximately 16 Mt (18 million st) of ore. Capital cost of the system has been estimated at \$18.6 million, including primary crusher installa-

Fig. 15. In-pit crusher installation, Twin Buttes mine.

tion, overland conveyor, and sampling plant located at the discharge end of the conveyor. In spite of problems encountered during the early months of operation, full production of 4.5 Mt (5.0 million st) per year was attained at favorable operating costs.

Bingham Mines of Kennecott Minerals (Copper)

Kennecott Mineral's (formerly a unit of Standard Oil of Ohio, then BP Minerals America, and now RTZ) Bingham mine started its operation in 1904. Since then, over 4.5 Gt (5,000,000,000 st) of copper ore, flux, and waste material have been removed. It is the first open pit mine in the copper industry, one of the world's largest mining operations, and has produced more copper than any individual mine in history.

Through 1981, ore milled plus flux amounted to over 1.4 Gt (1,500,000,000 st) with waste removed to dumps nearly 1.8 Gt (2 billion st) at a stripping ratio of 1.9 to 1. The total amount of copper produced in this period was over 11 Mt (12 million st).

The world's largest man-made excavation covers 7.28 km² (1900 acres). The pit measured 4 km (2.5 miles) wide at the top and it is over 0.8 km (0.5 mile) deep from the bottom to the top (Fig. 19).

Fifty-three 15.2-m (50-ft) benches in the mine vary in widths from 10.7 m (35 ft) to 38 m (125 ft). Kennecott's 1982 plan called for daily production rates as follows:

Material	Daily Rates
Ore	99 792 t (110,000 st)
Rail waste	40 824 t (45,000 st)
Truck materials	279 145 t (307, 700 st)
Total materials hauled per day	419 761 t (462,700 st)

On Feb. 11, 1981, a world record for hard rock materials blasted, loaded, and hauled during a 24-hr period was established. On that day, the mine trucks and trains hauled 579 382 t (638,649 st). In 1982, the stripping ratio increased to 3.1:1.0, with average copper content of ore being approximately 0.58%.

The Bingham mine features the most extensive rail haulage and loadout system in the world. In 1982 there were 153 km (95 miles) of standard gage railroad track all under direct centralized traffic control with 87 rail switches within the C.T.C. system and 36 under separate radio control. There are four entry points into the mine railroad proper: one switchback and three through tunnels. The rail cars are loaded directly by shovels at different strategic benches following the breaking of the rock (Fig. 20).

There were 39 electrical shovels varying from 4.6 to 20.6 m³ (6 to 27 yd³) capability and 58 locomotives (23 electric and 35 diesel-electric) in 1982. In addition, 98 haul trucks were used. These end-dump units varied from 59 to 136 t (65 to 150 st) in capacity.

Operating under the Utah Copper Div. of Kennecott, the Bingham pit is located 48 km (30 miles) southwest of Salt Lake City. The ore mined is shipped by rail into the concentration plant outside the pit 21 km (13 miles) north of the mine at the mouth of the Bingham Canyon.

Tailings from the concentrating plant are slurried to a nearby pond, where they have been stored since 1907. The pond now covers more than 2266 ha (5600 acres) and is 33 m (110 ft) high. More than 1.2 Gt (1.3 billion st) of material are impounded in the pond.

To further improve loadout operations, Kennecott embarked on an extensive study to explore the use of in-pit crushing and conveyor haulage. Until this could be imple-

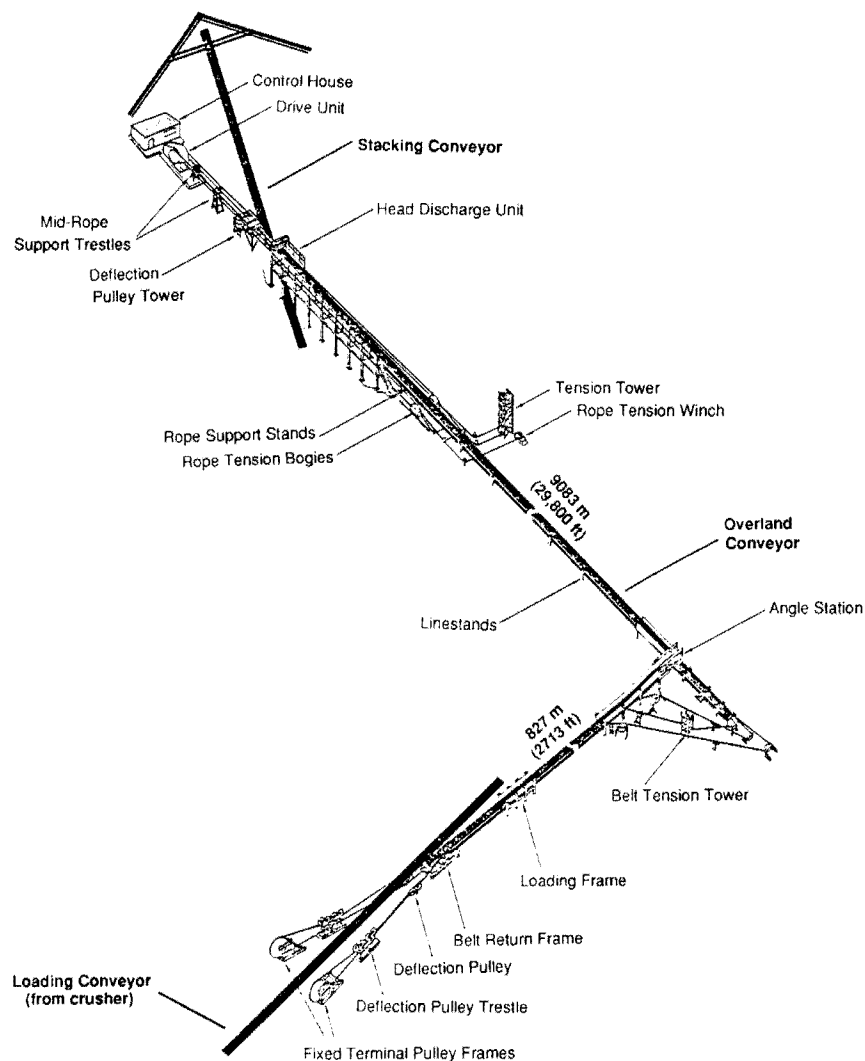

Fig. 16. Cable belt conveyor installation, Twin Buttes mine.

Fig. 18. Cutaway view of cable belt and wire rope support pulleys, Twin Buttes mine.

Table 5. Crusher System Characteristics Desired by Mine Personnel

Gyratory type
Large feedthrough capacity [3630 t/h (4000 stph)]
Freedom from clogging
Maximum frequency of moves: one/year
Average frequency of moves: once every two years
Large feed openings [1370 mm (54 in.) minimum]
Crush rock with compressive strength of up to 3520 kg/cm ² (50,000 psi)
High reliability of system 85% +
Freedom from bridging
Low maintenance cost
All-weather operation (−40°C to 40°C) (rain, snow) (−40°F to 120°F)
22 hr per day operation, 350 days per yr
Moderate noise
Dust control at transfer points
Operate with 12 to 15-m (40 to 50-ft) bench heights
Operate with 45-m (150-ft) minimum bench widths
Move up 10% maximum grades [15 m (50 ft) wide]
Relocation within two weeks
Surge capacity of 360 t (400 st)
Ideally compatible with trucks or trains
Minimum of conveyors, but also redundancy where possible

mented, all in-pit operations were converted to truck, leaving the rail system to serve ore haulage from the mine to the concentrators only.

Kennecott's \$400 million project at the Utah Copper Div. (UCD) includes in-pit ore crushing and the construction of new grinding and flotation facilities near the mine. The project incorporates some of the largest state-of-the-art crushing, conveying, grinding, and flotation equipment available in the industry (Fig. 21).

In the Bingham mine, a relocatable 1.5 × 2.7-m (60 × 109-in.) gyratory crusher (Allis-Chalmers) and conveyor system replaces the three rotary car dumpers and gyratory crushers at the Bonneville, Magna, and Arthur concentrators.

The existing 1000-car ore haulage railroad network is being replaced by an 8-km (5-mile) coarse ore conveyor system of 1.8-m (72-in.) wide belts which deliver ore from the mine to the new Copperton concentrator. The conveyor system has 12.9 MW (17,300 hp) connected, and a design capacity of 9.1 kt/h (10,000 tph). The crusher and conveyor systems were designed and supplied by PHB Weserhütte AG, West Germany.

The 70-kt/d (77,000-tpd) grinding facility includes three semiautogenous grinding (SAG) mills, 10.4 m diam by 4.6

Fig. 19. Bingham mine of Kennecott Minerals: One of the world's largest man-made excavations, covering 769 ha (1900) acres). Photo by Don Green.

Fig. 20. Rail cars being loaded directly by shovels at different strategic benches following breaking of the rock.

m long (34 ft diam by 15 ft long) and six ball mills, 5.5 m diam by 8.5 m long (18 ft diam by 28 ft long). These units are replacing 14 Symons crushers, 50 roll crushers, 5 rod mills, 50 primary ball mills, and 83 secondary ball mills.

The concentrator (flotation) contains 97 large flotation cells, including 33 85-m³ (3000-cu ft) WEMCO cells. This facility is replacing over 2000 small flotation cells.

Tailings from the flotation process are transported 21.4 km (13.3 miles) in a 1.2-m (48-in.) diam concrete-lined pipe to the existing UCD tailings pond near Magna, UT. The tailings pipeline, together with the copper concentrate and process water pipeline, are installed in a common corridor between the Copperton and Magna concentrator facilities.

At the existing Garfield smelter, a new pressure filtration plant receives concentrate from the 152.4-mm (6-in.) slurry pipeline, eliminating the need for rail transport of the concentrate.

Commissioning of the new facilities took place in early 1988, with completion in late 1988. Kennecott, formerly owned by BP Minerals America, is now owned by RTZ.

Mt. Newman Mining Co. of Western Australia (Iron)

Mt. Newman is one of the world's newest major iron ore operations. Started in April 1969, it is a joint venture between Amax Iron Ore Corp. (a subsidiary of Amax, Inc. of the United States) with 25% interest, Pilbara Iron Ltd. (a subsidiary of CSR Ltd., Australia) with 30%, BHP Minerals Ltd. (a subsidiary of The Broken Hill Proprietary Co., Ltd. of Australia) with 30%, Seltrust Mining Corp. Pty. Ltd. (a subsidiary of Selection Trust Ltd.) 5%, and Mitsui-C Itoh

Fig. 21. Utah Copper modernization project.

Fig. 22. Mt. Whaleback at Newman, Western Australia.

Iron Pty. Ltd. (a joint subsidiary of Mitsui & Co. Ltd. and C Itoh and Co. Ltd. of Japan, respectively) with 10% interest.

The operation features the world's largest single open pit iron ore mine, Mt. Whaleback at Newman, Western Australia (Fig. 22). Ore is hauled over a 426-km (265-mile) railroad to Port Hedland where it is processed, stockpiled, and shipped (Fig. 23).

By Mar. 31, 1983, Mt. Newman Mining Co. had shipped a total of 326 Mt (360 million st) of iron ore to Australia's BHP steel works and Japanese, Asian, and European steel mills. With the exception of the first two years of start-up operation, Mt. Newman has shipped 20 to 30 Mt (22 to 33

million stpy) of ore with 32 Mt (35 million st) being a record established in 1979.

Mt. Whaleback was originally a 5.5-km (3.4-mile) long hill rising 185 m (607 ft) above the plains. The mine can produce annually more than 40 Mt (44 million st) of iron ore and about 80 Mt (88 million st) of waste material. Typical daily total material movement is between 200 and 320 kt (330,693 and 352,740 st), of which up to 140 kt (154,000 st) of crushed ore is produced and railed to Port Hedland.

The 15-m (50-ft) benches are drilled by Bucyrus-Erie 60Rs. Blasted ore is loaded by 20 electric shovels varying from 7.6 to 18.5-m³ (9.9 to 24.2-cu yd) capacity. The shovels load a fleet of diesel-electric rear dump trucks for haulage to the crushing plant (Fig. 24). The total fleet comprises 52 109-t (120-st) trucks and 22 189-t (208-st) trucks.

Crushing and Rail Loadout: There are two crushing plants, which together can crush 160 kt/d (176,000 stpd) of ore through primary and secondary crushers to a 200-mm (8-in.) product for loadout.

Ore trains are loaded in two concrete tunnels. Two stackers rated at 4 kt/h and 5.5 kt/h (4409 and 6067 stph), respectively, form surge piles above each tunnel.

Each tunnel is served by a rail loop and a complete train can be loaded at 13.7 kt/h (15,102 stph) in either tunnel. A train is reversed into a tunnel until the locomotive driver is instructed to halt by an operator supervising loading operations on a separate two-way radio channel from a control cab high on the side of the tunnel.

In each tunnel, 13 openings equipped with chutes are lowered to gravity-feed waiting cars. As the cars are filled, the chutes choke automatically and are raised by pneumatic cylinders to the tunnel roof, depositing approximately 100 t (90 st) of ore in each car. When one set of cars has been loaded, the train is moved on and the operation repeated until the entire train has been loaded.

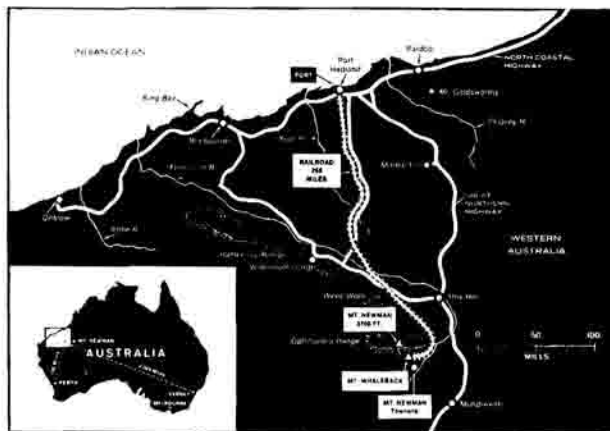

Fig. 23. Map of Mt. Newman and Port Hedland in the Pilbara region of Western Australia with railway connecting the mine and port.

Fig. 24. A large electric shovel dumps 50 t (55 st) of waste material into a 189-t (208-st) Haulpak on Mt. Whaleback, prime ore body of Mt. Newman Mining Co.

Fifty-two 2 680-kW (3593-hp) locomotives, 2000 110-t (121-st) capacity ore cars, and about 100 90-t (100-st) capacity cars are in use as of January 1983, to serve the railroad with a rated capacity over 48 Mt/a (53 million stpy) of ore. A typical train consists of 144 loaded cars drawn by three 2 680-kW (3593-hp) locomotives. Round trip to the port averages about 20 hr. Experiments are underway with 180 and 240 ore car trains using various locomotive combinations.

Port Operations: Port Hedland can accommodate ocean carriers varying in size from 5,000 dwt to 225,000 dwt, with maximum LOA of 315 m (1033 ft). Fully loaded draft at mean high water is 15.9 m (52 ft).

Rail cars are automatically positioned and rotary-dumped in one of the two car-dumping stations at Hedland at 104-sec cycle time [10 500 t/h (11,574 stph)] in the triple dumper, and 92.5 sec in the tandem dumper.

From the car dumper, ore is routed to a tertiary screening-crushing operation prior to stockpiling. Two screening-crushing plants feature 28 Allis-Chalmers double-deck screens and 12 Allis-Chalmers hydrocone crushers. Minus 30 mm + 6 mm ore comprises the lump product, -6 mm ore comprises the fines product. Plus 30 mm is fed to the crushers and recirculated back with fresh feed to the screens.

A computer control system continuously monitors ore flow, bin levels and trends, equipment availability, etc. It also has the ability to automatically stop or start the equipment as required by programmed parameters of the throughput in quality control.

Stockpiling, Reclaiming, and Shiploading: Four rail-mounted boom stackers [two at 4 kt/h (4400 stph) and two at 5.1 kt/h (5622 stph)] are in use at Hedland. Each of the stackers is equipped with a 48-m (158-ft) boom with a reach from ground level to 12.5 m (41 ft). The booms are slewable to form stockpiles on either side of the tracks.

A transportable conveyor rated at 2 kt/h (2205 stph) serves a 2 Mt (2,205,000 st) circular fines stockpile. The total stockpiling capacity at Hedland is approximately 9 Mt (10 million st).

Reclaiming of the ore at Hedland is accomplished by bucket wheel reclaimers [two 3 kt/h (3,300 stph) crawler-mounted, and two 6 kt/h (6615 stph) rail-mounted]. The booms are 14 m (46 ft) long.

The crawler-mounted units have 26-m (85-ft) discharge booms at the rear to feed into a self-propelled hopper car on top of the reclaim conveyor with 770 m (2526 ft) length

along the stockpile. The rail-mounted machines can slew 360° to reclaim ore over either side of the track.

At the end of the reclaim conveyor, an automatic sampling system can take up to 1497 kg (3300 lb) primary increments, on a 6-min time interval basis. Two 8130 t/h (8962 stph) shiploaders travel along a 658-m (2159-ft) two-berth ore pier. The largest ship loaded has been a 225,000 dwt bulk carrier. Two 160,000 dwt vessels can be loaded simultaneously.

The Carter Mining Co.'s Rawhide Mine, Gillette, WY (Coal)

The Rawhide mine is located north of Gillette, WY. Having commenced shipping in August 1977, it is one of the newest open-pit coal mines in the United States. Two seams of coal are separated by several meters (feet) of clay parting. The coal is approximately 30.5 m (100 ft) thick and is in turn covered by an average of 30.5 m (100 ft) of overburden. Initial mining is at the rate of 6.8 Mt/a (7.5 million stpy) to be ultimately increased to 22 Mt/a (24 million stpy). The area to be mined covers some 2428 ha (6000 acres), with an average stripping ratio of 1.3:1.0 to 1.6:1.0.

The 4.6 m (15-ft) thick upper level Roland seam is mined by front-end loaders into trucks. The 3-m (10-ft) parting underneath is also removed the same way. The 27-m (90-ft) Smith seam below is mined in two benches. The 18-m (60-ft) top bench is mined by a 26-m³ (34-cu yd) shovel and 9-m (30-ft) lower bench by a 16.8-m³ (22-cu yd) dragline.

The 163-t (180-st) bottom dump Unit Rig trucks are loaded by the shovels at 3.5-min cycles and by the draglines in 5 to 6 min. Two 15 to 18-m (50 to 60-ft) overburden benches are each 45.7 m (150 ft) wide. Removing overburden above the 1.6-km (1-mile) mine face takes approximately three months and uncovers 1.8 Mt (2 million st) of coal. Open inventory varies between 1.8 and 3.6 Mt (2 and 4 million st). Stripping is hauled by 145-t (160-st) rear-dump trucks, which can also be used for coal as required.

Once the coal is mined out, the land (overburden and topsoil) is returned to its approximate original contour. The reclaimed area will be restored to a condition equal to or better than its premining use.

Coal blending is carried out by selective mining at the mine face and at the loadout silos by dispatching trucks to particular loading locations based on customer quality specifications.

Truck dump facilities are designed for both bottom-dump

and rear-dump trucks. Presently the round trip from mine face to the dump station takes 8 to 10 min, under 1.6 km (1 mile) in each direction.

Originally there were four silos; two silos and a second rail loop were added in 1981. Each silo will accommodate one unit train. There is no other storage since open storage is prohibited in Wyoming.

6.11 Maintenance, Plant Facilities, and Utilities

6.11.1 Maintenance Systems

ROBERT N. McINDOO

INTRODUCTION

Maintenance systems use available materials, facilities, and the organization efficiently and effectively. Systems for maintenance such as preventive maintenance, planning, scheduling, and work sampling are not new; what is new is the computer to file and store data, produce schedules, and to provide timely information.

Some of the more important maintenance systems will be described in this section. Where applicable, the role of the computer will be defined. The systems can be made to function manually; however, the computer can greatly enhance the application in terms of man-hours expended and timeliness of information.

THE MAINTENANCE ORGANIZATION

The maintenance organization is at best a blueprint of how the department is to meet its objectives. The best organization plan can fail if the people are inadequate or their role is misunderstood. The most poorly conceived organization can succeed if the people expected to work within it fully understand implied responsibilities and are highly trained and motivated. Ideally, a maintenance organization is designed around the needs, the facilities, and the geography of the mine or plant, without regard to personnel. The ideal is seldom found. Generally, the ideal is conceived and then modified to meet the abilities, experience, and personalities of the personnel available.

Objectives

The primary objective of a maintenance department is to provide sufficient facilities and equipment in a safe operating condition, at the lowest possible cost, to meet the operating plan.

Maintenance may be called on to perform nonmaintenance work such as construction, plant modifications, equipment improvement, etc.; however, these activities must be considered secondary to the primary function when designing an organization. An exception to this would be the power distribution section of electrical maintenance. Pole-line construction and relocation is essential to the orderly progression of mining.

Functions

The maintenance organization is no different than any other organization in that it must perform certain management functions to be successful. The degree to which it performs these functions determines its ultimate success.

Planning—the activity that determines the goals of the department and the means to implement those goals. This would include planning for facilities, equipment, procedures, and most of all, personnel.

Organizing—the activity that distinctly identifies the work to be done and allocates it in the most efficient manner.

Leading—the activity that motivates the organization to meet departmental goals and to satisfy individual needs in concert with departmental needs.

Controlling—the activity that measures planned performance against actual performance. This requires detailed planning, maintenance standards, and monetary budgets.

Implicit in these managerial activities are personnel needs. This involves recognizing organizational needs and finding the proper people to fill those needs. Knowing the strengths and weaknesses of the individuals dictates the need for training.

Types of Organizations

Normally the maintenance organization has three levels of management:

First-Line Supervision—foremen who directly supervise the mechanics and craftsmen.

Middle Supervision—general foremen who supervise two or more first-line foremen. In large complex shops, there may be a lead foreman who directs shift foremen and reports to a general foreman.

Top-Level Supervision—maintenance managers or superintendents who direct the entire maintenance organization.

Generally there are maintenance planners, clerks, and maintenance engineers as staff to support the levels.

There are three basic types of organizations: (1) central maintenance organization, (2) area maintenance organization, and (3) central/area maintenance organization.

Central Maintenance Organization: This is a line organization generally built around craft skills and functions. See Fig. 1. This type of organization clearly divides work re-

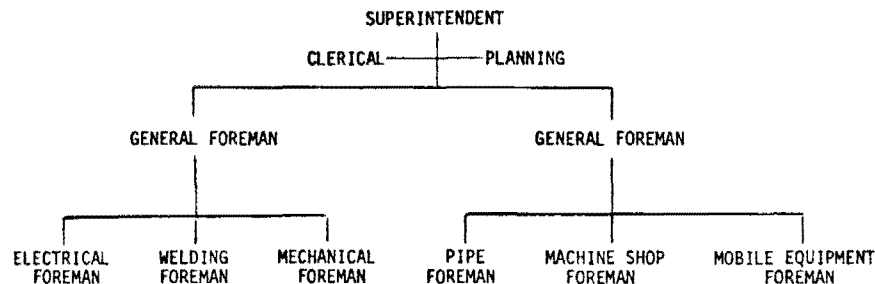

Fig. 1. Central maintenance organization.

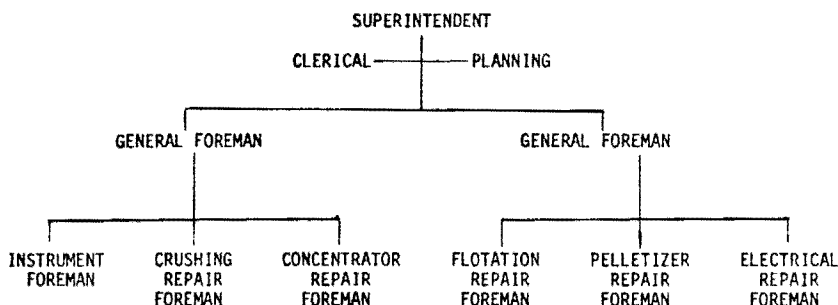

Fig. 2. Functional organization.

sponsibilities. It has the disadvantage of encouraging "in-breeding," that is, craftsmen tend to be promoted only within their group.

A variation of the centralized maintenance organization is the functional organization. See Fig. 2. This organization may or may not have some support from a central-shop group.

The pure area organization is seldom used. See Fig. 3. Generally, area maintenance is used with centrally controlled shop support.

Central/Area Maintenance Organization: This organization works well in a large operation which has defined plant functions and different mines or different ore bodies within a mine. See Fig. 4.

A variation of the preceding organizations appears where mobile equipment assumes a major responsibility for the operation. See Fig. 5.

In some surface-mining operations, all mobile-equipment maintenance and other field maintenance have been placed under the control of the mine superintendent. A separate central shops department performs support functions. This has the advantage of placing the responsibility for equipment condition on the user of the equipment. It has the serious disadvantage of possibly disregarding maintenance requirements in favor of short-term operational gains. The basic interests of the mine superintendent will inevitably favor operations to the long-range detriment of maintenance. Further, there is a conflict between the interests of the one maintenance group and the central-shops group. One may want improvements, modifications, or just reliability; the other's interests lie in the turnover of parts or overhauls.

Summary

The maintenance organization, like any organization, must be designed to meet goals and objectives. The form is

less important than the definition of roles and the adequacy and motivation of the personnel available to fill those roles. The type of organization is dictated by the size and geography of the operation as well as the degree and kind of maintenance involved.

TRAINING

To increase productivity, maintain efficiency, and to assure qualifications for advancement, the maintenance organization must provide training for both its craft group and supervisors. Technology changes. Today's skills become obsolete. Update to meet change is essential for both the craft group and the supervisors. The skills a foreman brings to his job are generally technical in nature. Knowledge of human motivation, group psychology, report writing, communication, and all the other managerial requirements are hardly inherent. New supervisors particularly need training, but all potentially promotable supervisors should be prepared for advancement.

Craft Group Update

There are three avenues for updating craft skills:

1. *Manufacturer's Training Schools*—Most manufacturers of mining and plant equipment have training schools to provide the basic understanding of their equipment as well as the hands-on maintenance required. These are generally excellent, but have the disadvantage of high cost. The sponsoring company must provide travel, housing, food, and in some cases, tuition for the training. A good approach is to send select supervisors to these schools and then have these supervisors hand-tailor the material for presentation to the craftsmen.

2. *Vendor Training Schools*—Oftentimes the manufacturer's vendors are prepared to provide training on-site for the craftsmen. This has the advantage of being less expensive.

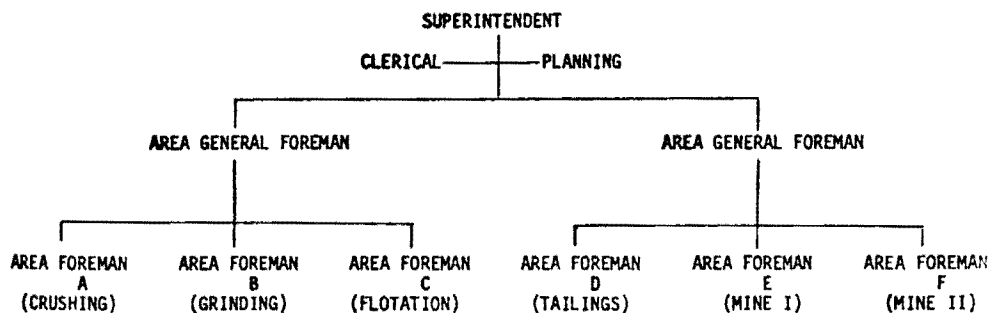

Fig. 3. Area maintenance.

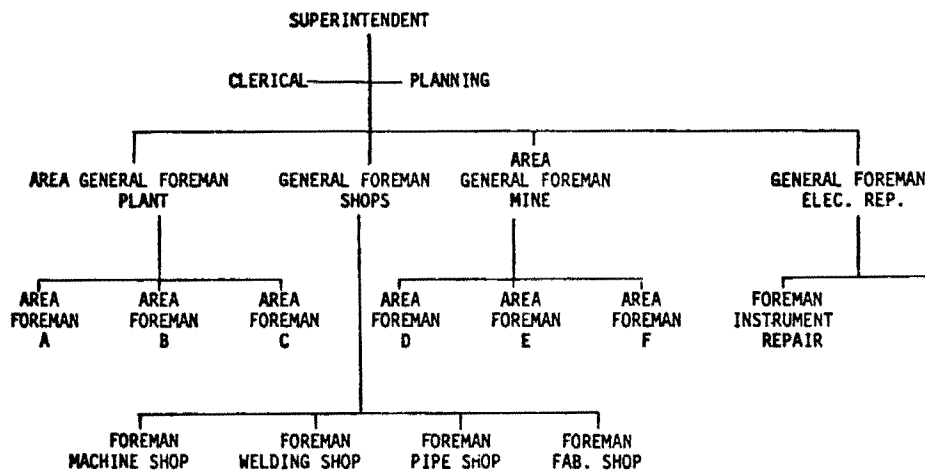

Fig. 4. Central/area maintenance.

However, this type of training should be previewed to assure conformance with company policy and capability.

3. *In-House Training*—In-house training programs, developed to suit particular needs, and presented by foremen or other supervisors, are the most successful and the least costly. Training aids, slides, film, and technical data can be obtained from vendors and original equipment manufacturers, but the program can be tailored to the needs and capabilities of the maintenance organization. Because the supervisor is, in effect, the expert, he gains in stature and credibility. Further, the followup on the job site then becomes ongoing training.

In order to prepare journeymen for training on new equipment, new techniques, and complex componentry, it is often necessary to provide training in basics:

Hydraulics—basic theory, valve operations, pumps, piping, and auxiliary components.

Bearings and Seals—types of bearings and seals, application, storage, and handling.

Electrical Systems and Controls, etc.

The areas of basic training should be tailored to individual organizational needs. Again, training in basics should be done in-house whenever possible.

Supervisory Training

Supervisory training falls into two categories: new supervisor orientation and preparation for promotion.

1. *New Supervisor Orientation*—The new maintenance supervisor is generally technically oriented and trained. However, he lacks managerial skills and needs help to bridge the

transition from *doing* to getting others to do. Some general areas for training would be:

- a) Motivation
- b) Common Problem Solving—typical problems facing the supervisor such as discipline, the reluctant worker, absenteeism, drugs, etc., and how to deal with them.
- c) Company Policies
- d) Union Contracts
- e) Management Skills—planning, leading, organizing, and controlling.

2. *Training for Promotion*—Annual evaluations, formal or informal, are a requisite to determine career goals for supervisors and to recognize the training to meet those goals. Promoting from within an organization develops *esprit de corps* and enhances morale. It is maintenance management's obligation to prepare potentially promotable supervisors to be qualified for advancement. Some areas where training may be helpful are:

- a) Technical—computer technology, metallurgy, etc.
- b) Accounting—cost-control techniques, budgets, cost analysis.
- c) Communications—speech, report-writing, conducting meetings.
- d) Industrial Relations—grievance-handling, arbitration, contract negotiation.

Training Methods

Training can be effective or a bore, depending on how it is done. Visual aids are all important. Movies, slides, and participative seminars are means to interest and stimulate

Fig. 5. Variation of maintenance organization when mobile equipment assumes a major responsibility.

thought. Under no circumstances should a script be read. Training is expensive. It behooves maintenance management to plan and execute training with the same attention to detail as for a plant overhaul. Training today is the key to tomorrow's success.

MANNING THE MAINTENANCE DEPARTMENT

No task facing a maintenance department is as difficult as justifying manpower. In operations, the manpower for an increase in production is rather straightforward: One drill operator, one serviceman, one shovel runner, five truck drivers, one crusher crew, etc., all from easily documented standards. But with the variety of crafts involved, maintenance has a much harder time. Then if production requirements increase, or worse, decrease, maintenance has an even harder time. Traditionally, maintenance has done a little guessing, or at best, used a certain rule-of-thumb to project crew sizes. But there are better ways.

Philosophy of Maintenance

The degree, or philosophy, of maintenance depends on a number of factors, not the least of which is distance from supporting vendors. The management of a mining operation must make a decision early on as to this degree: maximum, general, or minimum self-maintenance.

This decision will have a great effect on the maintenance workload, and hence the size of the department.

Methods for Manning

Backlog Method: In an established maintenance department, production increases or decreases are reflected in the shop backlog of work. With an effective work order system, this backlog is easily measured. A stabilized backlog of work equivalent to three to four weeks of man-hours is considered ideal. A rising backlog of 15 to 20% would indicate the need for more craftsmen; the number needed would equal the number of man-hours divided by hours per work week to restore the 3 to 4-week equilibrium. Similarly, a declining backlog would require consideration for reducing manpower.

The backlog is an effective tool for determining the number and kind of craftsmen needed for the work force. It has the advantage of being readily documented, but has the disadvantage of being a *responsive* measurement as opposed to an *anticipatory* measurement. It also presupposes the ability to increase or decrease manpower in the short run. Even if this were possible, it might not be desirable.

The backlog method is most effective for service shops where the work is somewhat discretionary as to timing.

Historical Data Method: The work of mobile equipment shops is for the most part nondiscretionary. Preventive maintenance inspections, servicing, and running repairs cannot be backlogged, although they can be preplanned (see the section on the "Work Order System—Planning and Scheduling"). Overhauls and component replacements can be planned and scheduled, but only with fairly large time-frame parameters. To provide the necessary manpower for these shops (and they include shovel repair, drill repair, truck and tractor shops, gas-vehicle shops, etc.), there has been developed another manning method using actual repair hour per operating hour statistics for each class of mobile equipment.

The computer accumulates the operating hours for each class of trucks, for example, and would also accumulate the repair hours charged to that class of trucks. It would then produce a repair hour per operating hour statistic for a period of time, usually a month, and a summary for six months and a year (see Figs. 6 and 7). The mining plan would indicate

Fig. 7. Welder, repair hour/operating hour.

tonnages or yardage that can be translated into truck operating hours. If there is a mix of sizes and kinds of trucks, the production requirements would be assigned first to the fleet with the highest availability, or greatest possible use, then to the next fleet with the second highest availability, and so on until the production requirements are met.

The fleet operating hours are then multiplied by the repair hour per operating hour statistic for that fleet. Each fleet will then generate the repair hours required to produce the operating hours assigned to it. The total of all the fleets would then represent the total repair hours (in this case, automotive diesel mechanics; see Fig. 8) needed under this operating plan. The same approach can be used for welders, shovel, and drill mechanics. In the case of a shop which services a number of mobile equipment shops, such as a machine shop, the repair hours needed would be the sum of the hours generated by multiplying the machinist's repair hour per operating hour for shovels, drills, trucks, etc. by the operating hours of that equipment.

These repair hours are then divided by a statistic that is the percent of the labor hours of a shop that historically has been expended on the equipment in the mining plan. For a truck shop, approximately 80% of the labor hours of the shop are expended on the equipment maintained by the shop. (The computer can easily produce this figure along with the repair hour per operating hour.) The remaining 20% is expended on project work, safety meetings, shop tools, and unmeasured equipment.

The repair hour-total now represents the needed total to meet the plan, including labor hours for construction, equipment modifications, safety meetings, etc.

To this total must be added absentee hours and vacation obligation.

Summary

During times of economic uncertainty, the production requirements may fluctuate greatly. It is imperative that the maintenance organization have a reliable tool to predict manpower needs. The repair hour per operating hour method provides such a tool (Fig. 9). It is reliable, dynamic, and flexible. As productivity improves, the repair hour per op-

3. Operating Hours Obtained from Mine Department Equipment Requirements.
4. Repair Hours are Automotive Diesel Mechanic Hours.

Fig. 8. Automotive maintenance manpower requirements.

erating hour reflects the improvements, reducing the statistic. As the equipment gets older, the statistic increases (see Fig. 10). Best of all, the logic of the approach is appealing to mine and plant management, eliminating the usual adversary posture toward maintenance manpower.

EQUIPMENT AND COMPONENT HISTORIES

Equipment and component records are essential to a maintenance organization. Records dictate the preventive maintenance program, control component replacement, in-

Fig. 9. Repair hour/operating hour for end dump trucks.

Fig. 10. Repair hour/operating hour for side dump trucks.

dicating the need for remedial investigation, and provide documented evidence for equipment replacement. Records can also be used to project major overhauls and thus maintenance budgets.

Good equipment and component histories can be maintained manually, but a manual system requires a prodigious amount of clerical time. The computer can eliminate that problem. With an appropriate software program, the computer is eminently qualified to perform record keeping with little or no paperwork.

The kind of information required will vary with the kind of equipment. The following data would be typical for mobile equipment, in this case, off-highway haulage trucks:

- 1) Unit number
- 2) Model and serial number
- 3) Basic specification: engine, transmission, wheel motors, etc.
- 4) Date in service
- 5) Total operating hours
- 6) Components
 - a) Engine serial number, previous rebuilder
 - 1) Operating hours since last change
 - 2) Date of last change
 - 3) Serial numbers of previous engines in sequence
 - b) Transmission serial number, previous rebuilder
 - 1) Operating hours since last change
 - 2) Date of last change
 - 3) Serial number of previous transmissions in sequence
 - c) Wheel motors
 - 1) Operating hours since last change
 - 2) Date of last change
 - 3) Serial number of previous wheel motors in sequence
 - d) Generator
 - 1) Operating hours since last change
 - 2) Date of last change
 - 3) Serial number of previous generators in sequence
 - e) Differential
 - 1) Operating hours since last change
 - 2) Date of last change
 - f) Drivelines, front, rear, interaxle
 - 1) Operating hours since last change
 - 2) Date of last change
 - g) Brakes, front, rear
 - 1) Operating hours since last change
 - 2) Date of last change
 - 3) Standard or XX drums by location
 - h) Hydraulic system, pump, left and right hoist cylinder control valve, kickover valve, flow control valve
 - 1) Operating hours since last change
 - 2) Date of last change
 - i) Radiator
 - 1) Operating hours since last change
 - 2) Date of last change
 - j) Steering system, pump
 - 1) Operating hours since last change
 - 2) Date of last change
 - k) Suspension, left front, right front, left rear, right rear
 - 1) Operating hours since last change
 - 2) Date of last change
 - l) Front axle, left and right: king pins, spindle, inner and outer wheel bearings
 - 1) Operating hours since last change
 - 2) Date of last change
 - m) Rear axle, left and right: spindle, wheel bearings, planetaries, bull gear, axle shaft
 - 1) Operating hours since last change
 - 2) Date of last change
 - n) Dump body
 - 1) Operating hours since last change
 - 2) Date of last change

Component changes are entered into the program on a daily basis. With this information, a glance at the CRT will give the current status of any truck.

Individual component histories are important to determine trends, predict overhauls, and to find the problem areas. Typical component records for trucks would include the engine and transmission histories, as shown in Figs. 11 and 12. Other components such as wheel motors, generators, final drives, etc. can be handled in a similar manner.

Basic equipment histories for plant equipment have been

of the inspection. Calendar-time inspections work well if operating levels are constant, but can cause problems when mine plans fluctuate. The use of calendar time leads to a tendency to overinspect during periods of low operations and underinspect when operations are at a higher level.

When devising checklists, equipment manufacturers, vendors, and lubrication suppliers can be most helpful. A word of caution: Equipment manufacturers and lubrication specialists generally have a tendency to "guild the lily," suggesting overinspection, so take their advice and adjust to suit (see typical mobile equipment checklists: Figs. 13, 14, and 15).

Structuring the Preventive Maintenance

Because preventive maintenance includes servicing, the program should include two levels of skills. The serviceman or oiler can be very helpful in providing information, but the actual inspection should be performed by a craftsman. Ideally, these two skills would work together.

There are two schools of thought on the craftsman selected to perform PM inspections.

1) PM inspections are considered an integral part of the workload, and assignment of the inspections is made to any qualified craftsman from the daily pool not committed to other work.

2) The PM inspections are assigned to specific individuals in the craft group who have an interest in and are trained for PM inspections.

Both approaches can be successful. However, in a large operation the problem of training a large workforce suggests selecting and training those craftsmen needed who have an interest in PM. Many good craftsmen make poor inspectors if their driving interest is in normal trade work. Some craftsmen will overinspect or underinspect. The PM inspector must

be able to distinguish between *worn* and *worn out*. It is much simpler to train a select group to apply predetermined reasonable standards of performance.

Scheduling Preventive Maintenance

Once the program has been designed, the problem of scheduling becomes paramount. Records for each piece of equipment must be maintained, correlating inspection with operating hours, tons, or whatever appropriate measure is used. This can be done manually, but is a natural for the computer. Programs can be designed to list each piece of equipment, hours since last inspection, those which are due for inspection, and any other pertinent data required, such as filter sizes, part numbers, oil quantities, coolant, and gear lube capacities, etc. Hard copies can be produced from on-site printers, which in effect become schedules. Operating hours and completed inspections are the input. The program can produce summaries of fleet or section PM performance, labor expended, etc., to provide maintenance management with a measure of the overall PM program.

Introducing the Program

It is essential that a preventive maintenance program, or any other maintenance system, have not only the blessing of management, but its whole-hearted support. The advantages must be cogently presented, with realistic quantitative cost benefits outlined.

Once this support is obtained, it is equally essential to consult with the operating superintendents. They must be convinced that the program is to their advantage. They should be involved in the decision process as to what equipment should be inspected, the frequency of inspection, and what flexibility is allowable to maintain production. With their cooperation, the program can be successful; without it, the PM program becomes only a maintenance problem, rife with maintenance vs. operating confrontations.

WAREHOUSE COMPUTER-AIDED PARTS REQUISITIONING AND DELIVERY SYSTEM

A maintenance program is only as good as its skilled craftsmen and supervisory organization. But a corollary to that is: a good maintenance program is only as effective as the availability of parts.

Generally, in most mining operations, maintenance determines the kind and quantity of parts required (maximum-minimums, or order points, order quantities), but is not directly responsible for the warehouse function. Cooperation between these two responsibilities is essential to the health of any maintenance organization and to assure obsolete parts do not build up in the warehouse.

The usual arrangement is to have a central warehouse or a central warehouse with satellite warehouses throughout the mine and plant to supply operations and maintenance. Withdrawal cards signed by supervisors are presented to the warehouse counter by craftsmen or service truck drivers for parts. Part numbers are obtained by supervision or the craftsmen from equipment parts manuals, with or without superceding part numbers or cross-referencing. The warehouse usually supplies a parts location reference which may or may not be obsolete. The cards would be punched for computer processing or would be manually sorted to provide inventory control and cost data.

This standard scenario satisfies only the function of warehousing and inventory control. Maintenance suffers from the many inefficiencies built into it.

1) Craftsmen travel to and from their place of work to obtain parts. Queuing at the warehouse is common. Work

sampling suggests that 15% of a craftsman's time is wasted obtaining parts (see "Work Sampling").

2) Supervision will spend from 25% to 40% of their time looking up part numbers in parts books, checking superceding numbers, or trying to cross-reference parts.

3) Parts that are normally in the warehouse may be out-of-stock. The craftsmen make the trip and come back empty-handed.

It has long been the maintenance manager's dream to have a complete up-to-date catalog of parts at supervision's fingertips, to be able to order parts remote from the warehouse, and to have those parts delivered to the job site. With the advent of the computer with remote cathode ray tube (CRT) audio-video display units, the dream has become a reality.

The first step requires the cataloging of every part in the warehouse. Parts are entered into the computer program by fleet and cost center, by all known part numbers including cross-referencing to other equipment, and by description of part and warehouse location. The catalog information appears as a screen on the CRT as shown by the inventory control main menu, Fig. 16 and detail screens, Fig. 17.

With this program, information screens may be called up by part number, description, location, equipment number, or cost center to determine if the desired part or parts are available in the warehouse. If they are available, the ordering screen, Fig. 18 is called up and up to seven separate orders can be placed. After entering the appropriate data (see instruction screen, Fig. 19), the order key is depressed on the CRT (Fig. 20), and a printer in the warehouse prints out a three-part order, Fig. 21. A hard-copy printout can also be obtained from the shop printer. The warehouseman puts up the order and, depending on location for delivery and size of order, delivers to the designated location by electric truck [0.4t (0.5 st) golf cart], forklift, or pickup delivery truck, Fig. 22. One part of the order form is retained by the warehouse. The other two parts are signed by the receiving responsibility, with one part returned to the warehouse as evidence of receipt. Warehouse inventories are adjusted daily to account for material received and disbursed. Cost accounting information is distributed to the proper accounts.

The delivery system can be set up on a regular time-delivery schedule. However, the ideal is delivery on demand. In a central-shop complex experience has shown that in excess of 100 deliveries a shift are possible using the demand system. Distances to receiving areas would be the determining factor.

The inventory can be adjusted as each transaction occurs providing current inventory status. The transactions can also be held and the adjustments *batched* every 24 hr. The *real time* approach is best for maintenance. The batching method provides better inventory control. Parts receiving by the warehouse also becomes a part of the overall program.

- INSTRUCTIONS-----FOLLOW EXACTLY AS STATED-----
1. Add charge to be used on & delivery point to order. Add all cost coding to order. Sight verify complete order. Hit PF1 again to transmit to Warehouse.
 2. If you wish to return to inquiries (not order yet) hit the PF2 key.

Fig. 18. Stores material withdrawal on the CRT screen.

DIRECT ORDERING OF PARTS GENERAL INFORMATION SCREEN

Here are some things to remember when ordering parts from the Warehouse.

1. Use the inquiry screens to find the items you wish to order. Key the class and location, quantity, unit of measure and a brief description of each item you wish to order.
2. If you do not need any inquiries to order any items you can proceed directly to the order screen and key in the items.
3. When filling in the cost coding on the items you wish to order, be very careful that you key it in properly. If you do not key any coding in for an item, it is assumed to be the same as the previous item.
4. When entering the quantity, remember to key in the leading zeros if you are ordering less than 10000.
5. One important thing must be remembered. No error checking is being done for you on any thing that you key in. If what you key in is not correct, your order will not be processed properly. So, in order to insure that your order is filled be sure to double check your order thoroughly before sending it to the Warehouse.
6. If you only have a 4 digit employee number, be sure to precede it with a zero when keying it in.
7. Whenever using the PF keys you must hold down the alter key at the same time.

-----HIT THE ENTER KEY TO RETURN TO THE MAIN MENU-----

Fig. 19. General information for direct ordering of parts on the CRT screen.

Fig. 22. Delivering the order.

Summary

The time lost procuring parts has a three-pronged effect; time lost by craftsmen obtaining the parts, the supervisor's time searching for part numbers, and the delay in completing the job itself. The computer-aided parts-requisitioning and delivery system will reduce labor by 15%, will reduce the time to perform the work a similar amount, and will give the foreman more time to supervise.

WORK-ORDER SYSTEM—PLANNING AND SCHEDULING

The most effective tool maintenance can have for the control of parts and labor is a functioning work-order planning and scheduling system.

An effective work-order system precedes planning and scheduling. The maintenance work order is an authorized document to perform a maintenance function or an improvement to equipment. Plant engineering work orders would be nonroutine capital or expensed work, such as construction, remodeling, or work entailing major expenditures and requiring detailed drawings. Both types of work orders can use the same format and procedures for handling.

Much has been written on the forms and procedures for a work-order planning and scheduling program. This section will detail in outline form one approach to the problem, utilizing the computer and CRTs instead of paper forms.

The advantages of a work-order planning and scheduling system are:

- 1) It provides preparation and planning to insure the effective use of labor and materials. With proper planning there are no surprises. Jobs are not started, then stopped for lack of materials. Work is scheduled and personnel are dedicated to the task. Planned and scheduled work is from 5% to 15% lower in cost.
- 2) It reduces downtime. Work is not interrupted. Crises do not develop. Equipment is returned to operations as scheduled.
- 3) Priorities are established. Essential work is done first. Each ordering responsibility knows when his work will be done. Flexibility of the system allows for changes as priority changes occur.
- 4) Supervision is relieved of details and expediting. Supervisors can depend on the system for detail planning, allowing them to function as supervisors.

These advantages of the basic system are much enhanced by utilizing the computer and CRTs to provide the memory filing, the work-order request, and the timely cost accounting. The computer can provide 48-hr cost data using the batch

method. If programmed for on-line data update, the cost information can be available on a shift basis. The cost information is intended to provide maintenance with the means to quickly evaluate progress of a project against current expenditures of labor and materials. Timely information can be used to correct problems before they become serious.

The system as outlined in the following distinguishes between the traditional work order for a fabricating shop, machine shop, pipe shop, etc., where there is generally discretionary time for planning and scheduling, as opposed to mobile-equipment shops, such as truck shops, shovel repair, drill repair, etc., where work is generated by preventive maintenance and breakdowns and is repetitive in nature.

In the traditional shops, work can be repetitive, but oftentimes it is unique, *one-shot* type of work requiring detailed step-by-step planning. The planning often requires more than one craft. The Work-order planning form (screen) allows for step planning and subsequent accounting so that estimates for each step can be compared against the actual.

The Mobile equipment shop work order would be processed in the same manner as the traditional work order, but because the work is repetitive, the work has been preplanned, defining work procedures, safety hazards, and parts lists (as outlined under "Mobile Equipment Work Order Request"). The intention of preplanned jobs is to provide the one best approach to the job and to expedite parts ordering (see "Warehouse Computer-Aided Parts-Requisitioning and Delivery"). In this case, each job will use the same five-digit work-order number but will have a sequential suffix number to identify each time the job is done. The program is designed to give the labor and material for each job performance, with an average of all previous jobs, thus providing an historical standard.

WORK SAMPLING

Mine and plant management are most happy with direct measurement of performance. A shovel produces so many tons per hour; a truck hauls so many ton-miles per hour; a drill produces so many feet per hour; and the total work force produces so many tons per man-day. Maintenance cost per productive unit based on labor and supply costs if reported on a month-by-month basis shown for a 12-month rolling period shows trends and anomalies that are important to management and that should be explained where they deviate from a normal or predictable pattern. But maintenance defies such direct standard measurements. The need for measurement is not just to satisfy management, but also to provide a tool to examine problem areas and to measure the effect of change. The simplest, most reliable, and least expensive measurement is provided by the technique of work sampling.

Theory of Work Sampling

Work sampling is a statistical-measurement technique which observes and records an *activity* at a point in time. Based on the laws of probability and the binomial distribution curve, work sampling states that the percentage of observations of an activity reflects to a known degree the average percent of time spent on that activity. Work sampling can be applied to any nonrepetitive activity, such as machine operation or product quality, but as applied to maintenance, it is basically concerned with human activity.

Activities to be Measured

The basic human activities of maintenance are (1) work, (2) travel, and (3) idle. These activities are often modified to include preparation, a necessity in any maintenance work,

and cleanup. Depending on circumstances, other activities may be added to further pinpoint problems.

Confidence Level

Reliability of work sampling is dependent on random observation and on a sufficient number of observations. Randomness is achieved by selecting the time of observation by random numbers or by throwing a die, and by varying the observer's route randomly.

The estimated number of observations required can be calculated after making some assumptions. A 95% confidence level with +5% tolerance limit is generally acceptable. The given activity, say *work*, is then estimated. The formula is then:

$$N = \frac{4(1 - P)}{E^2 P}$$

where N is the required number of observations, P is the percent of time activity occurs, and E is the element tolerance of error.

If we assume a craftsman's *work* activity at 60%, +5% element tolerance, we have:

$$N = \frac{4(1 - P)}{E^2 P} = \frac{4(1 - 0.60)}{(0.05)^2 0.60} = \frac{1.6}{0.0015} = 1067$$

This means that 1067 observations would have to be made to achieve a 95% confidence level with +5% error.

Observers

An ongoing work sampling program would normally be conducted by the industrial engineering department. Their technicians would be the observers and would produce the reports. There is an advantage to this arrangement in that the observer would be unbiased and trained as an observer. However, using supervisors as observers has the advantage of imprinting the skill of objective observation on them that they will consciously or unconsciously use from that time forward.

Using the Data

Work sampling does not of itself provide answers, but it can point out problem areas requiring methods improvement. When changes are made, working sampling can measure the effect of that change.

The following is a comparison of typical work-sampling results:

	A	B
% Work	41.5	58.5
% Travel	16.3	9.6
% Idle	27.5	24.4
% Preparation	12.1	6.4
% Cleanup	2.5	1.1

The initial study *A* indicated that travel was high and preparation was high, adversely affecting the *work* activity. A warehouse computer-aided parts-requisitioning and delivery system was installed. The results are shown in study *B*. The idle remains high, indicating further efforts are needed.

It is not uncommon for first-time work sampling to reveal a 35 to 40% work activity. The shock to the maintenance management can produce amazing improvements. As method improvements are applied to trouble areas, the work activity will increase from 10 to 20%.

Work sampling is a tool to be used in conjunction with other management tools. It is not a panacea. It is a happy

compromise between subjective observation and continuous certain time studies.

COMPUTER-AIDED DIAGNOSTICS

The advent of the microprocessor coupled with a computer can provide maintenance management with a means to diagnose the condition of engines, transmissions, hydraulic systems, or other componentry, quickly and surely. With appropriate sensing devices signaling the microprocessor (or directly to the computer), abnormal values are detected.

There are two approaches to providing the data to the computer: the static system and the dynamic warning and diagnostic system.

Static System

Hamilton Testing, Inc. has developed a static system for checking the condition of bus components and for component fault diagnoses. Pressure sensing transducers are external with a multiport disconnect to the bus. On-board sensors are brought to an electronic circuit box and interfaced with a computer device. Various tests have been programmed to provide high and low limits and actual test values. Unacceptable values are indicated on a printout with an asterisk. This system has not as yet been developed for off-highway mining equipment, although work is in progress.

The objection to this approach is that it does not measure the values under actual operating conditions. Too often problems that show up under operating conditions cannot be duplicated under no-load conditions in the shop. The main advantage is that all of the pressure-related sensors are separate from the unit, resulting in lower cost per unit and possibly greater reliability.

Dynamic Warning and Diagnostic System

A large taconite mining company and a communications manufacturing company have designed an automated Mine-Management System. The main purpose is to utilize computer software to optimize mine output and truck utilization while minimizing operating costs. Incorporated into the system is a microcomputer on-board each unit with appropriate sensors. These sensors signal on an exception basis, directed toward preventing catastrophic failures, or to signal a trend toward upper/lower limits. The signal would be sent to the sensor processor (microprocessor) and transmitted through a radio signal to the main computer and CRT display for appropriate action. The functions to be monitored are:

1) Engine speed	analog
2) Oil pressure	analog
3) Coolant temperature	analog
4) Transmission temperature	analog
5) Crankcase pressure (high)	binary
6) Coolant level (low)	binary
7) Oil level (low)	binary
8) Air restriction (high)	binary
9) Vehicle motion	binary

This system will be polled by the computer every 20 seconds to provide protection from catastrophic failures.

For diagnostic work, a "piggyback" microprocessor will be required. This will provide for additional functions to be measured and integrated against engine speed. For example, sensors will measure air restrictions after the air cleaner, ahead of the blower, and in the air box, thus pinpointing any air induction problems. The second microprocessor will also signal through the sensor processor whenever abnormal conditions occur. The piggyback processor will have a non-volatile memory and will be polled by the main computer.

The epitome of a dynamic system would be to have a software program that would take each troubleshooting problem through a step-by-step examination of the data until the cause is located. This concept is not too far from reality.

Other Systems

Cummins Engine Co. has developed a static system for engine diagnosis called Compuchek. Because of the unique nature of their fuel pump, they feel the system very closely simulates actual operation.

Summary

On-board diagnostics for trucks will be a reality. With nonvolatile memory and an appropriate interface, any maintenance department with access to a computer could use the system. With troubleshooting programs, diagnosing problems can be performed by technicians with "best mechanic" results.

6.11.2 MAINTENANCE EQUIPMENT AND FACILITIES

C. W. HOFFMAN

INTRODUCTION

Mine engineers or managers faced with the task of mine design and development have a unique opportunity to implement a long-term cost control program associated with the design and location of the mine maintenance facilities. It has long been recognized that as the size of mining equipment increases, so does cost per hour for downtime associated with the equipment. The type of equipment used will influence initial capital costs as well as long-term operating costs. The use of in-pit crushing stations and conveyors may reduce the need for diesel-powered equipment. The physical location of the maintenance facilities can either increase or decrease operating costs. The actual arrangement of the shop facilities can have a marked effect on the efficiency with which the shop may be operated. The choice of equipment used in the shop will also have an effect on the future operating costs of the mine.

Operating managers are now aware that maintenance is *not* a necessary evil. It is rather, an integral part of an operating facility and in many cases has a budget larger than that of the production group. The high initial cost of large, modern mining equipment and the growing cost to maintain this equipment require that careful consideration be given to maintenance facilities planning. The goal of management must be to construct these facilities at the lowest possible cost consistent with economical long-term operation.

This section will present fundamental considerations used to locate and design a surface maintenance facility that will enable maintenance to be carried out in a practical and efficient manner.

Major considerations in surface maintenance facility design are site selection, maintenance philosophy, mine equipment, building design and features, and shop equipment.

SITE SELECTION

Numerous factors will influence the location of surface mining maintenance facilities.

1. *Ultimate Pit Limits*—Obviously, it is undesirable to locate a large maintenance shop over the ore body and then have to move it at some future date. The maintenance shop should be located outside the ultimate pit boundary but not at such a distance that unnecessary travel time is a result.

2. *Mine Development*—The shop should be located in such an area that the access road from the mine to the shop will remain fixed for long periods of time. The projected development plan will have to be completed before the road system can be done. If possible, the shop should be located such that the access road is level or downhill from the mine.

3. *Natural Flow Point*—If a permanent crusher is to be used in or near the mine, it would be advantageous to locate the shop near the crusher. Caution about dust from dumping and crushing operations should be noted. If trucks or railcars are to haul directly to a milling facility, consideration will have to be given to locating the shop near or in the milling facility complex. Centralization of warehouse facilities and support shops such as welding, electrical, and machine shop could result in considerable cost savings. Whatever the case, the main service facility should be located near a natural flow point such as a crusher, mill, or dump.

4. *Ground Conditions*—An area that has good, natural drainage away from the mine should be considered. It is obviously expensive to do a lot of blasting and excavating if a large flat site has to be constructed on a rocky outcrop or ridge. This condition should be avoided if possible. Conversely, low or swampy areas should be rejected. Faulted areas where ground movement may occur should also be rejected.

5. *Climatic Conditions*—In northern climates, it is unwise to locate a shop facility on an exposed slope or ridge. If possible, roads should not be constructed on exposed ridges. In wet climates the opposite may be true and it would be unwise to locate the shop facilities in a drainage basin. Overall climatic conditions will influence building structure and will be discussed in another section.

6. *In-Pit Service Facility*—If an in-pit preventive maintenance (PM) service facility is planned, then the main shop can be located at a greater distance from the mine. If it is convenient, locate the main shop at the mill facility. Trucks, railcars, locomotives and other mobile equipment would only have to leave the pit for major service or repairs since PM and running repairs would be done in the pit. Equipment fueling would also be done at the in-pit service shop.

MAINTENANCE PHILOSOPHY

Corporate or personal maintenance philosophy will have an effect on the design of shop facilities. Factors such as the type of PM service, mechanical availability levels desired, budget considerations, use of outside vendors to perform maintenance services, and decisions based on mine life have an effect on maintenance philosophy developed at a particular property.

PM Service Philosophy

The type of PM service desired will have to be finalized prior to facility design. If a pit stop or assembly line-type PM service is to be used, a drive-through stall, ideally two bays long, will be needed. The total number of PM stalls needed will be determined by the size of the mobile equipment fleet. If PM is to be done in the mine, bays do not need to be provided in the main shop to perform PM service. In an effort to reduce travel to a minimum, the in-pit service center should be constructed with several *quick fix* or running repair bays. Again, fleet size will determine need.

Specific decisions as to where each type of equipment will be repaired need to be answered prior to facility design. More in-pit work means fewer bays will be needed in the main shop. If the majority of repairs will be done in the main shop, then space must be provided for those repairs.

Crew size and distribution will also affect facility design. Theoretically, maintenance forces distributed evenly on three shifts for a continuous operation should provide for the most economical utilization of plant facilities. In reality this does not work. Dislike of shift work and lack of management control are the most common reasons this approach does not work. The fact that bay space will not be utilized on the dark shifts should be taken into consideration when calculating necessary floor space.

Mechanical Availability

Estimates of mechanical availability need to be calculated in determining equipment fleet size as well as facility size. The size of the equipment fleet will determine the shop size. Generally speaking, each piece of equipment that is out of service for maintenance servicing or repairs should be allocated bay space. This includes such services as PM inspections, wash bay, tire shop (locomotive and car shops if there are railcars), fueling station, and load testing as well as running repairs and major repairs.

Equipment to be serviced in the mine maintenance facility will generally be all mobile equipment such as haul trucks, railcars, locomotives, loaders, dozers, water trucks, graders, cranes, and service vehicles. Availability calculations should be made for each vehicle type.

Budget Consideration

Foremost in the mind of the owner is cost and return on investment. This consideration will influence every decision to be made from feasibility studies to when to replace equipment and when to cease operations at the mine facility. Budget considerations will affect fleet size, equipment size, and type. Cost may dictate the equipment supplier. Since all mine equipment is not created equal, the selection of one equipment type over another may influence shop door width or crane height, which will in turn be reflected in facility changes and cost differences. It is probably best to design a *gold-plated* facility, then delete equipment and space, if necessary, at a later time when all budget figures have been assembled.

As much information as possible about operating costs and equipment availability should be gathered prior to making equipment selection. Operating mines are the best suppliers of this information.

Outside Services

The use of local vendors to provide various maintenance services will affect the size and cost of service facilities. The proximity to the site of these service vendors and the life of the mine are important factors. The cost of services is probably the chief factor. The decision is easily made if the mine is in a remote location and far from suppliers' services. The decision gets harder to make when the services are easy to obtain. Guaranteed availability by a supplier may change the fleet size, which may reduce necessary shop size. If the maintenance of specific pieces of equipment is contracted, it may be possible to reduce the number of service bays.

This is becoming more common when leasing equipment such as the gasoline-powered vehicles. If components such as engines and transmissions are to be rebuilt by the owner, a shop will have to be provided. If these components are to be sent out, this cost of construction can be avoided.

The amount of work done by outside contractors or vendors may also be a function of the availability of skilled maintenance employees in remote locations. It is possible that a large portion of maintenance work will, out of necessity, be done by vendor employees. This fact not only makes a difference in the facilities needed but also has a profound effect on the amount of control that management can exercise.

Mine Life

The economic life of the mine will play an important part in the design of maintenance facilities. Normally, long-life installations will be constructed with a view to performing maintenance services for the long haul. That is, the buildings will be heavier duty, more and better service equipment will

be installed, room for expansion will be provided, etc. Short pit life will dictate that everything will be built or purchased on a lowest cost basis even if cost to operate is higher. Generally, mines that have short-term pit life will have marginal or less than adequate facilities and most of the major maintenance and component rebuild will be done by outside equipment vendors. This is not necessarily wrong; management must decide if it is economically feasible to equip and train their maintenance forces to perform at a lower cost than that of vendor personnel.

MINE EQUIPMENT

The numbers and type of equipment used in the mine will have a direct impact on facility design. The amount of equipment will obviously be the largest factor in shop design.

In the recent past, the size of the haulage truck or rail fleet has dictated the size of the maintenance facility. This is true in most mines today, but in the near future, the ever-increasing alternate methods of materials transport will have a profound effect on haulage truck and rail usage. This reduction in haulage truck and rail will reduce the need for shop space and also reduce the number of mechanics needed to maintain the fleets.

When the mine plan is sufficiently developed, estimates of fleet size can be made. Initially, the number of material loading machines, usually shovels, is determined. This number is based on the overall tonnage proposed for the mine. In medium to large open pit iron ore or copper mines, shovels have been the most popular method of mining and loading ore and waste. Smaller open pit operators usually have a choice of front-end loaders, small cable shovels, or hydraulic shovels. Coal mines will probably use a combination of draglines, shovels, and front-end loaders. Tar sands, lignite, or other soft material mines may utilize bucket wheel reclaimers, draglines, shovels, and front-end loaders. Another choice of equipment may involve dozers with rippers and scrapers.

Generally, large, semi-mobile mining equipment is serviced at or near the working face and does not require a great deal of space in a central shop. A bay may be reserved for shovel and drill sideframe, boom, or stick repair, but that is mainly welding work and may be done in the welding shop. Since shovel and drill repairs are done in the mine, the maintenance facilities must be moved to the piece of equipment to be repaired. A mobile shop can be easily constructed by modifying one or more semi-trailers. One trailer could act as a mobile warehouse and would be stocked with commonly used spare parts such as nuts, bolts, pins, V-belts, filters, hydraulic hose, and pumps. Another trailer could serve as a mobile lunch room and would enable work to proceed without all the normal travel time associated with doing field maintenance work. Another trailer could be used as a welding shop and power center. Power would be taken from the mine electrical system and stepped down for tools, lighting, and welding equipment. For shovel overhauls, it is desirable to have a reinforced concrete pad with a pit located in the center so the gudgeon pin can be removed. Permanent jack pads and power outlets would also be a feature of this service pad.

After the mining equipment requirements have been determined, the method of ore and waste transport should be addressed (truck haulage, rail haulage, conveyors, or a combination of each). The most popular form is truck haulage with units ranging from 31.8 t (35 st) to 154.2 t (170 st). As a result of the present high cost of fuel, this mode of

transport will undergo radical changes in the future. The use of in-pit crushing and conveying of ore and waste will reduce the number of trucks needed. The use of trolley assist to speed up haulage can reduce fleet size. Some portable in-pit crushing schemes eliminate trucks altogether because the shovel loads directly into a crusher which feeds a conveyor system.

However, in the near future, trucks will still be the most popular method of transporting ore and waste, although fleet size will be down as a result of the previously mentioned equipment. The size of the trucks will most generally be determined by the shovel or loader size. The number of trucks will be determined by factors such as rated production, mechanical availability, length of hauls, in-pit haul grades, etc. The economic advantage of size is well known in haulage truck selection. It still takes one driver to operate a 31.8 t (35 st) truck as well as a 154.2 t (170 st) truck. Labor costs for operations, as well as maintenance, can be greatly reduced by using fewer, larger haulage trucks.

On the other side of the coin, however, the impact on production is greater when a larger haulage truck is out of service than a smaller unit. This places increasing pressure on maintenance forces to provide more in the way of services to operations.

Maintenance forces must be given the tools to provide this increased service level. These tools include: a management philosophy committing maintenance personnel to improved productivity; improved employee training; maintenance management systems that work; preventive maintenance programs that stress failure prevention; effective repair procedures designed to correct known deficiencies; and effective tools and supplies.

BUILDING DESIGN AND FEATURES

In this section, facility design will generally be based on a worst case approach. That is, the general discussion will be based on the design of a hypothetical remote shop location where the mine needs to be almost self-supporting. Components will be rebuilt on site, personnel will be local, and vendor participation will be minimal. The operation is basically a shovel and truck haul system.

Mines located in warmer climates can eliminate all obvious cold weather details. It is obvious that more consideration be given to drainage in tropical climates than the dry southwestern United States. Lighting will have to be much better in cold weather buildings than those located in the South because skylights and translucent panels cannot be used. Mines where local, outside contractors can perform rebuilds and overhauls of equipment components economically can omit component rebuild facilities.

Individual components of this hypothetical facility will include buildings, truck shop, in-pit service shop, machine shop, welding shop, electrical shop, component rebuild shop, automotive (gasoline shop), central warehouse, change and lunch room facilities, and administrative office.

The central factor involved in the design of the maintenance facilities is efficiency. This should be the prime consideration with each function of the facility. The natural flow of personnel and equipment should also be a prime consideration. Unless built-in travel time for both personnel and equipment is kept to a minimum, an efficient and cost effective maintenance program cannot be realized.

All the various maintenance functions that will take place at the facility should be reviewed as a unit so that flow mistakes are not made. Building locations and the location

of shops within those buildings should be designed to eliminate bottlenecks or backtracking.

In most cases it is advantageous to combine all maintenance services into one building except for in-pit PM services. In the far north this is done automatically to conserve heat but it does not always satisfy the travel time component. Experience shows that services buildings in warm climates tend to be scattered about with no apparent reason for their location.

Lost productivity resulting from mechanics' travel time can be as high as 2 or 3 hr per day, counting coffee breaks, lunch, washup, start of shift and end of shift time, and several trips to the tool crib or warehouse. Two or 3 hr is a realistic number. It is difficult to design everything around the mechanic's change room but that is the general idea. The largest group of mechanics should be located centrally to the change room and warehouse. Generally, a *T*-shaped building with the shops located in the horizontal bar of the *T* and offices located in the vertical bar will satisfy this criteria.

A variation of the *T* design is to produce a *U* or semi *U*-shaped shop configuration. This will give more shop space for cargo equipment fleets but still satisfy the criteria of keeping mechanic travel time to the minimum. A *U*-shaped shop with drive-through truck bays at one end will satisfy those individuals who want to avoid "trapping" haul trucks when another truck parks on the apron in front of an occupied bay. In a well-run shop there is little chance that this situation will occur.

Generally mechanics leave their work areas for breaks such as lunch and coffee, trips to the restrooms, consultations with their supervisor, and to draw parts and supplies from the warehouse. The proximity of the work stall to the lunchroom and change room will reduce travel time to these two areas. Travel time to the restroom can be reduced by placing minimum service units in the outer limits of the shop. Some travel to the warehouse can be eliminated by: utilizing phones and a parts runner; storing fast moving low cost items out in the shop; preplanning work and delivering parts prior to the need; or scheduling high parts usage work in bays close to warehouse issue windows. (For a computerized system, see Section 11.1).

Buildings

Generally, the mine maintenance buildings will be preengineered structural steel frame buildings. In severe winter climates the buildings will be clad with factory insulated wall panels composed of factory finished steel skins bonded to an insulated core. The roof will be built up of a smooth, single ply elastomeric membrane applied over a metal deck and sloped to aid in runoff removal.

A parapet roof over the large shops is recommended in snow and ice conditions to reduce chances of ice fall. Drains located inside the shop walls will insure that freeze ups are eliminated. Leaving the perimeter of the roof uninsulated for 0.9 to 1.2 m (3 to 4 ft) will promote melting and eliminate ice buildup behind the parapet.

The lower buildings in the complex will utilize a sloping roof with a large overhang to protect personnel from snow and ice falls. Doors should be protected with sloping ice shields.

Buildings constructed in warmer climates will have uninsulated ribbed prefinished metal siding and roofing. It is the practice in warm climates to leave 1.8 to 3 m (6 to 10 ft) at the bottom of shop walls without sheeting. This may be a good practice for processing plants but it is not good

for shops. Dirt is a destructive agent and must be kept out of all shops.

In particularly hot climates, insulated walls and roofs may be necessary in reducing shop heat. Makeup air cooled by evaporative systems and contained by using rollup doors may lead to a more productive shop. Shops in warm climates may use translucent panels to provide additional lighting to the work area. Northern facilities cannot afford the heat loss through the uninsulated panels.

Shop lighting, especially in the high bays, is not as simple as it appears. Generally the truck bed and upper deck prevent direct overhead light from reaching the important lower frame components. This makes inspections and repairs more difficult. High bay lights should be 1000 watt high-pressure sodium for maximum illumination at the lowest cost. The light spacing should be closer than for a machine or welding shop. Additional lighting should be used in the PM service bays to aid in frame and component inspections. This lighting should be about 2.4 m (8 ft) off the shop floor. All internal walls should be finished in a gloss white or light beige to reflect as much light as possible. This will also prevent dust or exhaust smoke buildup. Finally, portable 250-watt mercury-vapor units on small stands should be provided on an as-needed basis.

Heating in the far north is usually an expensive proposition. Generally, natural gas will not be available so fuel oil will be the probable fuel source. Shop heating in the large shops can be done with a composite of forced air unit heaters and radiant heaters. Forced air ducted down to floor level between each door works well in controlling heat loss and delivering heated air to the equipment and personnel. Radiant heat panels on inside walls supply heat to areas in the center of the shop.

Heating in the in-pit service shop will, of necessity, be supplied by radiant heaters. This is because the doors will be cycling much more frequently than the doors of the main service shop and warm air will escape. Hot water heated floors may be a partial answer to the in-pit service shop heating problem.

Heating in offices and lunch and change rooms can easily be done by radiant means, either electric or hot water. If a hot water system is used, thought should be given to heating the shop floors.

Truck Shop

The haulage truck repair shop will consist of numerous bays or stalls reserved for truck repair. Historically, the bays have been side-by-side and only one bay deep. Many recently constructed truck shops are two bays deep and the trucks are parked facing each other. Space conservation, mechanic travel time in big shops, heat conservation in northern climates, and reduced "trapping" are all reasons for this design change. Obviously a fleet of less than 10 to 15 trucks can utilize the side-by-side arrangement. The drive-through double stalls are more suited for larger fleets.

Assembly line PM techniques utilize work stations located in a row with specific services performed at each station. The trucks are moved and the mechanic is stationary. This type of service can be done either at an in-pit service shop or in the central shop. Large mines may need several service lines to allow for either daily or weekly service. A drive-through shop two bays deep is ideal for this type of service concept.

Bay Size: The bays should be constructed for the largest truck deemed feasible for use during the foreseeable future regardless of initial design size. As ore grades diminish and

haul distance increases, it may become necessary to replace the original fleet with larger trucks. The bays should be 3.7 to 4.6 m (12 to 15 ft) wider than the truck to allow for service and movement around the truck. Parts that are removed and need to be replaced can be stored in the area beside each truck. The need to remove tires and wheel motors requires that sufficient lateral space be provided in each bay. Space for movement of service equipment such as forklifts or portable type cranes should be considered.

Bay length can be determined by adding truck length plus engine module length and 3 m (10 ft) for service work space. Some length should also be included for fleet upsizing or model changes. The length should be calculated with the bed in the lowered condition.

Column location should not interfere with component removal such as the engine module. The overhead crane should be able to work over the complete unit during repairs.

If drive-through bays are used, such as two bays where trucks would be parked facing each other, an aisle 3.7 to 6 m (12 to 20 ft) wide can provide access between the trucks and will not require crane support. This center lane can provide forklift access as well as access for foot travel. If this transportation aisle is provided, then the area directly in front of each truck can be used for part storage as well as a space to provide mechanic tool storage.

Work benches should not be placed between stalls. Most work benches become storage racks for new and discarded parts that eliminate space for work surface. Each mechanic should have a large roll-around tool box. These boxes can be modified to include a work surface where small components can be cleaned and repaired. Normally, components are removed and replaced in a repair bay. The component is then repaired in a component repair shop.

Bay Height and Crane Supports: The floor to crane hook distance of the truck bays is an important matter. The overhead crane should be able to clear a raised truck bed with the hook completely raised. Reducing the crane clearance height is an invitation to disaster, and should not be considered as a means to conserve construction funds.

The truck shop crane(s) should have sufficient capacity to remove large components such as engine modules and rock boxes. It is preferable that the shop cranes have a main hoist and a high speed auxiliary hoist for light lifts. In large shops, it is preferable to have two cranes in each crane aisle to prevent lost time waiting for crane support. The cranes should be either pendant or radio operated. There is little call for full-time crane operators.

Bay Doors: The door openings should be 1.5 to 1.8 m (5 to 6 ft) wider than the widest part of the truck. The edges of the opening should be protected by ground level steel or concrete wheel guides. These guides will prevent expensive accidents and should not be omitted. In northern climates, sectional doors seem to provide the best service. They are simple to maintain and are insulated to provide some heat retention. Large rollup doors seem to have guide problems and are less resistant to high wind forces. Door height should be 1.2 to 1.5 m (4 to 5 ft) higher than the maximum truck height with the bed down. Doors designed to open high enough to accept trucks with the bed up should be avoided.

Floors: All shop floors should be reinforced concrete, 203 mm (8 in.) thick. The top surface should have hardener additives to protect it from chipping or cracking. The surface finish should be smooth so as to allow for ease of cleaning. A rough surface promotes oil and grease buildup. All walkways and storage areas should be painted with an abrasive

resistant epoxy surface. The area directly under the trucks may be left unpainted.

A floor drain should be located in the center of each bay to carry away water and fluid leaks. The main header for all the drains should be directly under the drains and should have no elbows or low points to allow for sand buildup. The floor drain should run to a sand sump outside the shop building where a front-end loader can remove accumulated sand and mud. A weir should divide the sump and an oil skimmer should be provided to contain oils and solvents. Oil from the skimmer should be piped to a buried sump which can be drained by vendor or plant forces.

Other Factors: The oil sump can be piped to a shop-wide oil recovery system. Each bay would have quick disconnect type fitting in the floor near the front one-third of the bay. A drain hose could be attached to the engine and the oil removed by air pump. A flush-mount quick disconnect cap would cover the fitting when not in use. A portable pan on wheels with a hose connection could be used if a tank or oil line is to be drained.

A sloped reinforced concrete apron with hardened surface should extend one and one half times the circumference of a truck tire [approximately 15 m (50 ft)] to provide for tire cleaning prior to the shop entrances. The apron should have embedded railroad rail runways to reduce concrete damage.

An area to park mine equipment must be provided near the truck entrance to the shop. This storage area should be sufficient in size to park from one-third to one-half of the fleet size.

To increase shop productivity, hose reels providing engine coolant, engine oil, hydraulic oil, grease, and air should be placed at the top end of every second bay. Coolant and lubricant supplies should be stored in bulk tanks buried in a convenient location at a building end. Grease should be supplied in bulk 1814 kg (4000 lb) containers.

Water outlets and welding outlets should be conveniently located between bays. Oxy/acetylene hose reels connected to a central system eliminate costly bottle handling.

The number of repair bays necessary to service the truck fleet will be proportional to the fleet size and estimated mechanical availability. At least one bay should be available for each truck that is out of service for maintenance. A 40-truck fleet with an estimated mechanical availability of 70% would ideally require 12 service bays. These bays would not all be main shop but would include other places where a truck could be serviced such as PM service bays, tire shop bay, wash rack, and engine load test area.

The average worldwide availability figures for haulage trucks are in the range of 65 to 70%. Using 65 to 70% availability would be conservative in designing a shop and would allow for bad weather such as fall and spring thaw conditions in the Northern Hemisphere and monsoon seasons in the Pacific areas. Bay space will have to be provided for support equipment such as water trucks, motor graders, front-end loaders, rubber-tired dozers, mobile cranes, track dozers, and any other large pieces of mobile equipment. The addition of these types of support equipment can double the size of the truck garage.

In-Pit Service Shop

A service shop located at the edge of the pit will increase productivity by reducing travel time for fuel, PM services, and small running repairs. The intent is to keep all mine equipment at the mine unless it needs maintenance that will require more than 4 hr or so to complete.

The size of the in-pit service shop will vary depending

on the amount of equipment that is serviced on a daily basis. All rubber-tired equipment should be fueled and inspected on a daily basis. The complete fleet should then be scheduled for PM inspection on some repetitive cycle. One method is short duration frequent PM checks on a 125-hr interval (weekly). Another method is to see the equipment less frequently for a longer period of time. Either way, all parts and supplies that will be needed to perform the scheduled PM services must be stocked at the pit service shop. Generally those supplies are oil and air filters, V-belts, lights, mirrors, horns, electrical relays, and all consumable fluids such as oil, fuel, and coolant.

The service shop normally performs four functions: (1) daily fueling and lube checks; (2) weekly or bimonthly PM inspections; (3) running repairs (4 hr or less); and (4) tire service.

These functions should not interfere with one another. That is, lube and fuel service is done in specific bays, PM checks are done in another area, and running repairs in another. The tire service area will also be in a separate bay.

The bays in the service shop should be served by an overhead crane of 4.5-t (5-st) capacity. The minimum lifting height of a crane should accommodate a raised bed of a haul truck.

The fueling and lube service bays should be equipped with hose reels that supply liquids such as fuel, engine oil, hydraulic oil, coolant, grease, water, and air. Where possible, automatic filling systems should be used to speed service and to avoid contamination. Several systems are available and each has specific advantages. A boom-mounted hose cluster for fuel, hydraulic, and engine oil that can be attached to a similar connecting cluster of piping at a single point on a haul truck can speed service.

The PM service bay, which will be used for 125-, 250-, and 1000-hr inspections should not be used for running repairs. Equipment will be scheduled in at preset times and any delays in moving equipment out will delay more vehicles. Other bays are provided for running repairs. To support this pit-stop type of maintenance scheme, all spare parts or supplies which can be utilized in a short duration service of 1 to 2 hr should be stored where the mechanic can readily obtain them. To avoid lost time issuing parts, they must be in open stock.

The tire shop should be part of the in-pit service shop. A double bay large enough to allow a large forklift to change haulage truck tires is a requirement. A tire tear-down and assembly machine is necessary and can be located in the bay next to the one in which the equipment is parked. In warm weather, the tires can be changed on the apron to the tire shop.

Design of the truck wash bay should receive special attention. In warm climates it need only be a large slab of concrete sloping into a settling sump with a 1034 kPa (150-psig) water supply. It is also desirable to have a raised catwalk on each side of the wash bay. Cold weather design is a much more complex problem.

A large bay, one and one-half times the normal width, will be necessary for a wash bay, used in the far north. The extra width is necessary because the wash attendant needs to be able to stand away from the equipment while he is hosing it down. Medium pressure [1034 kPa (150 psig)] and high volume is necessary to remove dried mud. A high pressure, hot water cleaner will also be needed to clean areas such as the engine, hydraulic pumps, tanks, and other oily areas. High pressure hot water is also necessary for degreasing prior to painting.

The floor should drain to the center and then out the side of the building via a covered launder to a sand settling sump. The sump should be large enough to be cleaned by a front-end loader. An oil skimmer will also be needed in the sump.

The building should be of drive-through construction and the exit door should point toward the front of the in-pit service shop to reduce travel time. The building construction should be the same as the rest of the shop with a ceiling height higher than a raised truck bed. A catwalk should be constructed on each side of the shop to allow for cleaning of the upper parts of the haul trucks. The wash bay is sometimes used as a thawing shed so the normal heating equipment requirements need to be upgraded. Large quantities of heated air are required to dry a truck that is being prepared for service. Large unit heaters are the solution.

SHOPS AND EQUIPMENT

Machine Shop

When it comes to the machine shop, most mines over build. That is, they supply the shop with too many machines and then hire machinists to run them and then make work for the machinists.

The modern maintenance machine shop should only do maintenance work, not production work. A mine should purchase pins, shafts, bushings, etc. Maintenance work is removing and replacing worn parts, not making new parts. A place for a moderate sized machine shop may be provided, but do not fill all the open space with expensive, unused equipment.

A mine maintenance machine shop should have some basic machine tools and may include:

- 1 lathe with 610-mm (24-in.) swing
- 1 363-t (400-st) hydraulic press
- 1 large drill press
- 2 small drill presses
- 1 305-mm (12-in.) cap cutoff saw
- 1 large pedestal grinder
- 1 small pedestal grinder
- 1 key seater
- 1 small milling machine
- 1 portable boring bar

Normally, remotely located mines can have parts sent out for repair and returned in 90 days. Sufficient warehouse stores will reduce the need for expensive machine shop tools and operators.

All machine shops should be designed with material flow in mind. Dirty parts enter one end and clean parts leave the other end. A steam cleaner or high pressure, hot water cleaner should be located in the disassembly area. Sufficient floor space should be provided to work on several projects at once. The area where the machine tools are located should not be directly under the crane path to the assembly area.

Purchase only that equipment for which a future use can be determined and justified. Rely on the spare parts inventory and factory represented rebuild service. A machine shop is not a warehouse in which to store parts. Aisles should be painted around machines and shop. Because the weld shop produces abrasive dust from arc-air cutting, the machine and weld shop should be separated.

The machine shop should have high pressure sodium bay lighting and light colored, reflective walls as do the other shops. An overhead crane with a 13.6-t (15-st) main hoist and 4.5-t (5-st) auxiliary hoist will be sufficient for most cases. A forklift should be part of the shop tool list.

Weld Shop

The weld shop, as the machine shop, should not be considered a spare part production shop. It should be designed as a maintenance or repair shop and should be sized and equipped accordingly.

The weld shop should be large enough to accept a haulage truck rock box and several shovel dippers at one time. Generally the shop should have a large work area at one end, smaller work areas along a central aisle at the other end, and metal working machines along both sides of center in the middle of the shop.

This design provides for ease of access to all shop machines but gives some order to welders working on small projects in booths at one end, away from others using an arc-air gouging tool on a dipper bucket at the other end of the shop.

Shop equipment may include:

- 4 600-amp welding machines
- 6 400-amp welding machines (MIG)
- 1 3 m × 12.7-mm (10 ft × ½-in.) capacity press brake
- 1 3 m × 12.7-mm (10 ft × ½-in.) capacity shear
- 1 large pedestal grinder
- 1 small pedestal grinder
- 1 ironworker
- 1 305-mm (12-in.) rolls 19 mm by 1.2 m (¾ in. by 4 ft) capacity
- 1 12.7-mm (½-in.) drill press
- 2 welding rod heaters

The weld shop should be provided with lighting similar to that of the machine shop. The walls, however, should be clad in a light-colored, sound-absorbing material. As arc-air gouging is a source of objectionable sound, attempts should be made to reduce this source.

Crane service over the welding shop should be able to lift a haul truck box or a shovel dipper. The auxiliary hook should be 4.5-t (5-st) capacity.

Electric Shop

Generally speaking, the electric shop of a moderately sized open pit mine does not need to be a large shop off by itself. Motor or generator problems that can be solved without rewinding are generally mechanical, such as replacing bearings, welding and turning shafts, and cleaning and inspecting. For this reason, the electric shop should be located in an area of the machine shop. Many motor components are repaired in a machine shop, then transported for reassembly back to the electrical shop so it is natural to make the electrical shop part of the machine shop.

The instrument repair portion of the electric shop should be an isolated room where benches can be set up so electronic components can be tested and repaired. Cleanliness is an important precondition for electronic work. The cost of many of the test instruments also requires that they be located in a semi-secure area.

Component Rebuild Shop

The decision to rebuild components vs. sending them out for repair should be a deliberate one. For a component rebuild shop to be cost effective, it must be able to compete with vendor and local shops. This is normally difficult to do if the mine in question does not have a sufficient volume of work to allow the component rebuild shop to be competitive with the vendor or contractor. This means if the number of pieces or components to be rebuilt is small, then a contractor or vendor can supply these components at a cost far less

than a mine operation can rebuild the component for themselves.

If some components are to be rebuilt in-house, sufficient work benches and sufficient area should be provided for the miscellaneous components to be rebuilt. Support equipment for rebuilding components depends on the type of components to be rebuilt and should be installed accordingly.

Automotive (Gasoline Shop)

The general shop facility requirements for large production equipment also apply to gas vehicles. Some special consideration for these small units are:

1. A hydraulic hoist capable of raising a 9-t (10-st) truck bed should be considered.
2. A duct or trench system to remove exhaust gases to prevent the accumulation of carbon monoxide. A system of sealed trenches in the floor, connected to an exhaust fan with openings for each stall is most convenient. A metallic hose is inserted into the trench and attached to the vehicle exhaust pipe. An overhead duct system can be used if an overhead crane is to be excluded.

Central Warehousing

Storeroom or warehouse facilities should, if possible, be planned to adjoin the section of the maintenance shops that have the greatest need for spare parts. Sufficient spare parts must be kept on hand to allow for minimum shop service. Parts coverage must cover the time period for components to be shipped, repaired, and received.

The warehouse itself must be planned to facilitate handling of materials with the least amount of effort. High-use items, possible fasteners, mobile equipment repair parts, bearings, seals, and belts, should be stored where they are easily accessible—requiring a minimum of travel for disbursement. Access aisles must be provided for forklift trucks, and bin aisles must be of proper width to accommodate two-wheel or four-wheel hand trucks, a minimum of 0.9 m (3 ft).

Receiving areas should be provided with sufficient space to accommodate forklift unloading of trucks. A recessed truck platform-level ramp contained within the building will provide all-weather loading and unloading of trucks and is desirable in spite of the floor space it requires. In cases where rail deliveries are anticipated, it is desirable to include a boxcar-level ramp for unloading and loading with a forklift.

Material storage requirements must allow consideration for both size and weight of materials. Therefore, storage capacity must be determined with great care. Compartmental drawer-type cabinets should be provided for very small materials, and steel adjustable shelf cases should be planned to accommodate other varied sizes of materials. Heavy adjustable pallet racks with engineered safety factors for carrying capacity must be provided for very heavy materials.

Other considerations for storage must include special cabinets for gaskets; door-type cabinets for materials such as bearings, seals, and other items which should remain relatively dust or dirt free; and cabinets with lock doors to contain high value security items or items on which the issue must be strictly controlled.

Special racks must also be provided for cables, ropes, rolls of gasket materials, and other commodities that require special handling because of odd shapes, lengths, or safety in handling.

Consideration must also be given to storage of acids, lubricants, compressed gas cylinders, bulk of bagged materials, steel, and heavy wear or repair materials. Generally for safety reasons or because of their bulk, these items cannot be stored in the warehouse proper and will require outside storage or storage in buildings suited to the material. Heating such a building is unnecessary, but a heated building is desirable for lubricants and other fluid materials, some of which cannot stand varied temperatures. Again, in providing for such special storage, provision should be made for railroad access with boxcar level ramps or docks that will permit forklift unloading and a crane facility to provide for unloading heavy materials from gondola-type cars.

In addition to adequate storage facilities, stress should be placed on a cataloging system. A placement or commodity numbering system must be provided that will lend itself readily to easy determination and ability to find materials. This system must be determined with the knowledge that warehousemen are generally in-house trained, but often do not have an accounting background. Visiline, Visiguide, and other cataloging aids are very helpful in this area.

Lunch and Change Room Facilities

Amply designed and centrally located change rooms and washrooms can reduce lost time in the shop. Circular wash fountains are space savers and are easy to clean. In general, all materials used for washrooms should be selected with ease of cleaning and maintenance in mind. Ceramic tile or the less expensive glazed tile brick make excellent wall and floor materials.

Change room size would be determined by the maximum number of employees per shift. There should be one urinal and one water closet for every 10 to 15 employees. A good ventilation system should be provided. Change rooms and eating space (lunchrooms), are generally combined, but separated from washrooms. Expanded metal front lockers allow clothes to dry. Each maintenance worker should have one locker, and for those who work both inside and in the field, two lockers are needed.

Administrative Offices

Shop supervision requires the privacy of an office. Clerks with files, office equipment, etc., must have a convenient, comfortable place to work. If planned carefully with the shop, offices can be a valuable adjunct. Some points to keep in mind are:

1. Offices should be central to the shops.
2. The office of the shop foreman should be located adjacent to the shop and be large enough to accommodate small meetings.
3. An outside entrance is desirable.
4. Good lighting and many electrical outlets are needed.
5. Ceilings should be of acoustical material; walls and floors should have surfaces that can be easily cleaned.

SUMMARY

Maintenance facilities, as well as the overall mine development, should be given considerable planning and thought. Well-planned, well-designed shops which are custom built to an individual mine's needs will reduce the overall maintenance cost of the operation, which in turn, will reduce the overall operating cost of the mine, allowing a maximum profit for the operating company.

6.12 Health and Safety in Surface Mining

6.12.1 General Overview

DOUGLAS W. HUBER

DEFINITION OF HEALTH AND SAFETY

The subjects health and safety are closely related. Health, simply defined, is freedom from illness and disease. For surface mining the definition of health includes positive control of the miners' exposure to potentially harmful toxic dusts, chemicals, radiation, and noise. Such control is obtained through proper design and operation of the mine.

Safety is defined as being free of conditions that may lead to mental or physical bodily injury or the destruction of property. For surface mines the definition of safety includes all miners' activities ranging from slips and falls to protection from electric shock, machinery, eye injury, and drowning. Safety also deals with individual miner's impulsive behavior, attempts to shortcut safe work procedures, or acts of bravado.

In a broader sense safety includes training of miners also. Since any mining activity or work can be conducted in numerous ways, training is required to insure that objectives are met. Such training should emphasize doing the work safely along with doing the work well. A natural relationship exists between working safely and productively. Since miners, like all workmen, do not always instinctively work safely, a well executed training program yields multiple benefits.

MANAGEMENTS' ROLE IN HEALTH AND SAFETY

The foregoing definitions of health and safety include aspects of management involvement. Surface mines, similar to other industrial activities, are operated by management for profit. Management brings together and controls workmen, materials, labor-saving devices, and energy to produce a salable product with profit as a fundamental and necessary goal.

The conduct of activities which take place must be controlled within a framework of moral and legal obligations, at the lowest possible total cost. The overall cost of mining must remain low if the mine is to be competitive, to yield profit, and continue to stay in operation until its reserves are exhausted.

Any management decisions made will obviously affect this continuity in many ways. Managers, like miners, need training in order to make correct decisions. No decisions are more important than those that affect the welfare of the miners.

Managements' Function

Management controls the productive climate developed at any mine, or for that matter, any assemblage of workers in any industry. Part of any busy, producing activity is worker attitude toward health and safety. It can be said that miners' attitude is the key to safe, productive mines, and management controls the key. No adversary relationships can be allowed to exist which involve health and safety issues.

One difficulty in establishing and maintaining a health and safety program in surface mines is the appearance that hazards do not seem to be great. In fact, when compared to underground mines, surface mines are relatively safe places to work (see Table 1, Sec. 6.12.2). However, it is just such

relative comparisons that can contribute to complacency regarding health and safety in surface mines. Any accident or occurrence that is *noticeable* must be treated with the same concern and action used for *actual* incidents of injury or property damage. Complacency and general acceptance of occurrences and "near misses" as being part of the job must be guarded against by management. All accidents are merely higher-order occurrences and near misses. Such accidents become definable because of injury (and human misery) and identifiable dollar value of property damage.

Management must monitor and control its own and the miners' notion that workers' accidents are part of the job. The mere fact that accidents just seem to happen does not justify acceptance of accidents as unavoidable. Such acceptance of accidents is probably *the* major problem in surface mining health and safety.

Managements' function is to *control* and thus meet those objectives established through formal planning. A safety policy, signed by top management and containing sufficient operating guidelines, is a basic mine management control function.

Evolution of Management Involvement

In the early days of mechanized surface mining, management consisted of two or three men who concentrated all of their management talents on excavating dirt and rock in order to expose the valuable material. Techniques and equipment evolved that yielded amazingly low unit mining costs. This "no frills" approach was dictated by declining deposit grade in some cases or competition for markets plagued by wide swings in market price. A conservative, and often too narrow, overall management style evolved due to continuous economic stress.

During this early stage of mechanized surface mining only two major functions were recognized: (1) the removal of waste rock and dirt, and (2) the loading and hauling of the valuable product to a place of processing and end use.

During the course of the foregoing surface mining development the so-called "rising expectations" of society (following the Korean War era) was also evolving. Broad concerns for human rights and man's effect on the environment focused attention on the need for changes in traditional surface mining systems. Concern for the welfare of miners and environmental protection has had considerable impact on surface mining.

As will be discussed in the following pages, legislation was enacted for improving conditions in underground coal mines. Later legislative attention was directed to metal and nonmetallic mines. Following an underground coal mine disaster, additional federal laws were enacted to improve health and safety in coal mines. Surface mines, although relatively safe, were carried along in the fervor to make all mines safer and healthier places to work. Additional legislation followed, covering training and other safety aspects of all mines. Legislative attention to environmental concerns has had a similar impact on surface mines.

Newer concepts of management were adopted by the mining industry to assist survival. As costs for mined products increased, prices obviously rose also. Predictably, domestic mines that were marginal (mainly due to low ore grade) closed in favor of higher grade and less costly international sources. Some mining localities suffered and the future for some domestic mineral sources is not promising.

From the simple two-function approach to surface mining of earlier times, a more complicated division is required. These are suggested to be:

- 1) Environmental studies and premining surface preparation.
- 2) Waste material removal and placement.
- 3) Mineral excavation, loading, hauling, and processing.
- 4) Environmental protection during and following mining, including surface restitution.
- 5) Planning and conducting health and safety functions, including training, during the mine operating cycles.

Managements' Current Position

It may be argued that surface mine management has always had a concern for health and safety, even though virtually nothing was written about it. Some managements undoubtedly included health and safety intuitively as part of the two basic functions mentioned earlier. However, modern surface mine management has learned that the effects of poor control of health and safety are too important to be so ill-defined. The health and safety of the work force bears as directly on the economic well-being of the mine as waste-to-ore or overburden-to-coal ratio does.

From a strictly legal viewpoint, a mine possessing reasonable economic feasibility becomes an economic liability if legally closed down for poor safety performance. Less dramatically, safe mines are productive mines. It is generally recognized in industry that most mines with high yields of product per man-day also have low accident rates. These mines are well-managed and examples can be found of such mines which operate profitably in all segments of the mining industry.

Training Responsibility: Decisions on how best to accomplish any task bear directly on the quality and quantity of work performed. Usually, work techniques acquired through experience are passed on from supervisors and senior workers to those newly hired. Occasionally new methods arise, are tested, and used, rejected, or modified. This informal training process is historic, and it works, but does not develop the full potential of the work force. Supervisors also need training, usually by outside trainers, such as provided by mining equipment manufacturers. Management must assist by providing time, training facilities, and such expert training assistance to supervisors.

A formal training program can be based on the mandatory federal regulations as stated in Part 48, Title 30 CFR. This training should be continuous and of high quality. It should capture the imagination of the trainees and use site-developed ideas and techniques. With proper control, methods for improving equipment operating techniques, based on job safety analyses, will always include safe procedures and easier ways to accomplish the task. Periodic evaluation (depending on type of task) of effectiveness of the training will indicate modifications required.

Results of such training are often noteworthy. The fact emerges that highly productive mines are safe mines, with low miner turnover and absentee rates.

Training Records: Training should be documented in as direct and simple a fashion as possible. Periodic reviews of

training records, when coupled to records of safety performance (MSHA inspection results or accident statistics) or operation costs, will indicate areas needing improvement. Any improvement needed can be set as a goal and training emphasis shifted to accomplish this change required.

Training records tend to stand as evidence of care taken by management to improve health and safety and miners' environment. While some record is mandatory (MSHA regulation), management can use the information to improve and protect supervisors, the individual miners, and the mining system.

The Cost of Health and Safety

Studies that have been conducted into the cost of health and safety at surface mines understandably suffer from a small data base and lack of uniformity in accounting methods. This lack of data stems from the competitive nature of most mining and the obvious differences that exist in surface mining. However, one such study (Johansen, 1978) of a sampling of US surface coal mines indicates that accidents accounted for 47% of the total cost of safety. (Total safety costs are considered to be direct and indirect costs, including estimates of cost of lost production time following accidents.)

Although conditions will vary from mine to mine, health and safety costs, excluding special training and personnel-type costs, can be assumed to be in the range of 2 to 6 % of the total cost of production in surface mines. This percentage includes the cost of accidents, but excludes cost of major catastrophes and large compensation and property damage payments which are unusual in surface mine experience. However, whatever individual surface mine health and safety costs are, substantial dollar amounts can be saved by reducing accidents.

Cost saving through accident reduction is a reasonable management goal. However, it overlooks the improvement in productivity possible when employees recognize company concern is personal and directed toward them as individuals.

No figure for cost of health and safety can be estimated that covers the human misery that accompanies any accident. Both mental and physical injuries can occur which have no price tag; neither can a dollar asset figure be placed on safe mines. Such mines have an aura of well-being. They are highly productive, have a stable work force, and good relations with customers and neighbors.

In summary, top level management attention to health and safety is part of its overall responsibility. This attention yields positive results in the mining organization's stability, efficiency, and ultimate profits.

The following list states the basic conditions required for safety at surface mines:

- 1) Top management's commitment to health and safety as evidenced by a signed statement of policy.
- 2) Integration of health and safety into all management functions from evaluation of managers, right down to specific miners' work procedures.
- 3) Supervisors trained in cost implications of health and safety and provided with training assistance.
- 4) Inspection and recording of workplace conditions and work procedures by supervisors each work shift.
- 5) Reporting system to management of all *near-misses* and *accidents* with responsible *investigation* and *action suggestions*.
- 6) Internal health and safety inspection system, including supervisor and miner participation.
- 7) Scheduled evaluation of health and safety status.

LABOR ORGANIZATIONS' ROLE IN HEALTH AND SAFETY

From a historical perspective, concern for health and safety began in underground mining. Surface mining was limited to small deposits and specialty systems such as dredging that did not present the hazards of underground mining. The underground miners themselves recognized the dangers of their work and probably were the first source of stimulus for improving safety conditions.

No discussion of the subject would be complete without recognition of the contribution to health and safety by these historic members, their organizations, and their contemporary counterparts.

Most early mines had organizations that were developed and supported by the miners for their mutual benefit. With virtually no safety regulation in the early days, mines were operated with little understanding and, probably in some cases, regard for the needs of the miners. Hence, miners' organizations were formed to fill this need, which varied considerably from one mining camp to another.

Most of the many present mining labor unions developed from earlier miners' organizations. Wages, work rules, benefits, and safety provisions were issues that attracted new members. Some miners' unions developed into sophisticated organizations which today control large sums of money from retirement and health benefit funds. Such unions, composed of large numbers of individual miners, wield influence at the ballot box in both national and local elections. Politically, the labor vote, and this includes the miners' unions, has had a significant impact in elections and on health and safety legislation enacted.

Labor Union Impact

Mine health and safety laws and subsequent regulations contain the indelible imprint of union participation in the regulatory process. The many-sided lobbying efforts that yield the rules under which the mining industry operates is on-going and has produced dramatic results in the past 15

years. Certainly the miners' unions have substantially influenced this noteworthy achievement.

It would be unfair to single out specific unions since so many have participated over the years. Perhaps the coal mining unions could claim the major role since the regulations are most stringent for coal mining. However, this claim is also offset by recognition that underground coal mines have the highest disaster potential due to gas and dust ignition and a generally weaker rock environment.

Health and safety regulations reflect the differences between coal and noncoal mining by the existence of separate rules for each. Limited distinction was recognized for the differences between surface and underground mining, which may be surprising. Many of the surface coal mining regulations reflect underground mining concepts and conditions. This parallels the existence of strong underground coal mining unions and indicates the strength of the position of the unions during the rule-making process.

Labor organizations currently use health and safety issues as a major part of day-to-day operating procedure. In some instances tangible improvement in safe working technique is obtained. In others, a clouding of real issues, not totally based on safe procedures, takes place and true safety progress is hindered. In general, however, the miners' labor organizations have promoted health and safety to the benefit of the individual surface miner. This, of course, yielded benefits to the firm and industry also.

Labor Union Future Involvement

Improvement in surface mining health and safety statistics is the commendable goal of surface miners' unions. Experience in well-managed surface mines clearly points out that the well-being of the miners is best served when a non-adversary relationship exists between the union, the mine management, and the regulatory agency: MSHA (Mine Safety and Health Administration).

Until mutual trust and good communication exists between the three parties, real progress in advancing the cause of surface mine health and safety at any given mine cannot be made.

6.12.2 The Federal Role in Health and Safety

LEO MISAGI

INTRODUCTION

Federal legislation aimed at collecting and distributing statistical data and improving health and safety in the mining industry was enacted at the beginning of the 20th century. Before that, miners and the United States public seemed to accept the unsafe working conditions as natural, and risk-taking as part of the job. Each new mine disaster has prompted a new legislation related to mining. The progress of recent years in mine safety and health has done much to change the old fatalistic attitude toward hazards of mining.

HISTORY

The Organic Act of 1910 (Public Law 179, 61st Congress) had established the US Bureau of Mines to deal directly with the issues of mine safety. Further milestone in the same direction was the 1941 law that required inspection and investigation of health and safety conditions, accidents, and occupational diseases in coal mines (Public Law 49, 77th Congress).

Mine Safety Code for Bituminous Coal and Lignite Mines, issued in 1946, was the first formal set of federal mine safety regulations, still without requirements for enforcement. The 1952 law, aimed at prevention of major disasters in coal mines, empowered federal inspectors to write notices of violations and orders of withdrawal in cases of imminent danger (Public Law 552, 82nd Congress). The 1966 amendments to the latter law have extended mine safety and health regulations to small mines—any mine in which no more than 14 individuals are regularly employed underground (Public Law 376, 89th Congress).

The first legislation dealing directly with issues of safety and health in metal and nonmetallic mines was enacted in 1961. It authorized a study of the causes of accidents and the means of prevention of injuries and health hazards in this category of mining (Public Law 300, 87th Congress). It was followed by the 1966 law that required inspections of metal and nonmetallic mines, enforcement of standards, closure orders for imminent dangers, promulgation of new health and safety standards, establishment of a standard advisory committee, state plan provisions, and special emphasis on occupational health problems (Public Law 577, 89th Congress).

Penalties for violations, and fines and imprisonment for willful violations were provided in the Federal Coal Mine Health and Safety Act of 1969 (Public Law 91-173, 91st Congress). This law contained mandatory health and safety regulations, required the promulgation of standards, periodic inspection of mines, closure orders for imminent danger, and notices for violations of standards.

The most recent mining legislation—Public Law 95-164, 95th Congress, titled Federal Mine Safety and Health Amendments of 1977—amends the 1969 Federal Coal Mine Health and Safety Act (Public Law 91-173) and repeals the Federal Metal and Nonmetallic Mine Safety Act of 1966 (Public Law 577, 89th Congress). Briefly, the current law

- Eliminates the disparity of protection between coal and noncoal miners and between miners and other workers of the nation.

- Retains the health and safety standards set up by the previous acts for coal and noncoal mines.

- Strengthens the means for compliance with the law.
- Emphasizes protection of miners' health.
- Provides new procedures for assessing civil penalties for violating mine health and safety statutes and regulations at all mining operations.

- Calls for broad mandatory training of all US mine workers.

- Sets up new procedures for the rule-making process.
- Gives a greater role to miners or their representatives for improving their health and safety.

- Establishes an independent Mine Safety and Health Review Commission outside the Department of Labor to hear contested citations and withdrawal orders, thus eliminating the conflicts created by allowing the administering agency to review its own actions.

- Requires the operators to maintain records of exposure to toxic substances, of employee training, as well as other useful records.

- Prohibits discrimination against miners who complain about safety and health, take part in actions, or exercise their rights under the Act.

- Entitles miners to be rehired and reinstated to their former positions with back pay and interest.

- Holds liable any person discriminating against a miner for all expenses incurred by the miner in bringing a discrimination complaint.

- Retains the provisions in the 1969 Coal Mine Act for limited state participation in mine safety and health enforcement and expands its scope to include noncoal mines.

- Allows states to enforce standards that are not in conflict with federal standards.

- Transfers the mine safety and health authority from the Department of the Interior to the Department of Labor to eliminate the long-standing jurisdictional conflicts between the two agencies.

INSPECTION OF MINES

The Mine Safety and Health Administration (MSHA) of the US Department of Labor is the federal agency in charge of inspecting and investigating of health and safety conditions in the nation's mines. An MSHA inspector must have documents identifying him/her as representative of the US Secretary of Labor, who has the right to enter any mine to make any inspection or investigation. Like all employees of the United States government, MSHA mine inspectors are expected to maintain high standards of ethical, moral, and other conduct in enforcing the laws and regulations related to mine safety and health.

In cases of dispute between labor and management, an inspector is impartial; unless specifically directed by their supervisors, inspectors are not required to cross picket lines or make an inspection or investigation of the mine. Inspectors are not required to sign the forms designed to release the company from responsibilities related to safety and health at the mine. Inspectors are not to perform any work at a mine, or assist any employee or mine official in the performance of production-related jobs. Inspectors are there for in-

spection, investigation, and discussions directly related to occupational safety and health.

Mining activities and conditions at the time of inspection should represent the routine. Inspection of mines and mills on idle work shifts are limited to areas where conditions are practically the same as they are on the active shifts. Advance notice of an imminent inspection is prohibited by law when the purpose of inspection is to detect any imminent dangers that may exist at the mine and determine whether there is compliance with the mandatory health or safety standards or with any citation, order, or decision issued under requirements of the Act. Advance notice is allowed if the inspector intends to gather information about the mandatory health or safety standards, or obtain, utilize, and disseminate information relating to health and safety conditions, the causes of accidents, diseases, and physical impairments originating in such mines.

A representative of the operator and a person representing his fellow miners must be given the opportunity to take part in inspection of the mine and the conference related to it. A pre-inspection conference is held to inform the operator and the miners' representative what the inspector wants to do. A post-inspection conference is held to inform the parties involved about the inspector's findings.

The law prescribes two regular, complete inspections for every surface mine in the United States. Additional spot inspections are made to determine the status of citations, notices, and orders issued during a previous inspection, or to collect additional samples and monitor potentially hazardous conditions.

MSHA inspectors investigate any health and safety complaints brought to their attention prior to or during an inspection. They also conduct a special inspection of the mine if their office receives a written complaint about conditions of health and safety or an imminent danger threatening the lives of miners.

The US Code of Federal Regulations—Title 30, Mineral Resources—and the inspection and investigation manuals for federal mine inspectors contain detailed information on mine inspectors' duties. Copies of these can be obtained through the US Government Printing Office.

HEALTH AND SAFETY STATISTICS

The Safety and Health Technology Center of MSHA in Denver, CO, collects and publishes various statistics related to mining. The latest data on mine safety and health can be obtained by writing to Mining Information Systems Division, Denver Safety and Health Technology Center, Mine Safety and Health Administration, P.O. Box 25367, Denver Federal Center, CO 80225.

Tables 1 and 2 show the injury incidence rates in the United States and the number of injuries in surface mining, coal and noncoal, classified by industry and types of accidents. Both tables were adapted from *Mine Injuries and Worktime Quarterly* published by MSHA's Mining Information Systems Division.

Terms Used in Safety Statistics

Incidence Rate is the number of injuries per 200,000 employee-hours, rounded to two decimal places. **Fatal** injuries are those occurrences resulting in death. **NFDL** (non-fatal with days lost) injuries are nonfatal occurrences with lost workdays, that is, nonfatal injuries that result in days away from work, statutory days charged, or days of restricted work activity. **NDL** (no days lost) injuries are occurrences having no lost workdays, that is, nonfatal injury occurrences

resulting only in temporary loss of consciousness or medical treatment other than first aid.

According to the generally accepted classification, accidents may be the result of contact with energy sources such as mobile equipment or moving parts of stationary equipment and machinery, electricity, explosives, compressed gases, caustic chemicals, flame, extremely hot or cold surfaces, toxic and noxious substances, injurious radiation (ultraviolet, ionizing); being struck by or against other objects; being caught in, on, or between other objects; being rubbed or abraded by friction, pressure, or vibration; falling to the same or other level; being engulfed by solid material, liquid, or gas (including drowning); suffering from overexertion; and bodily reaction to a voluntary or involuntary motion.

ORGANIZATION OF THE MINE SAFETY AND HEALTH ADMINISTRATION

The Assistant Secretary for Mine Safety and Health in the US Department of Labor has two administrators—one in charge of coal, and the other, metal and nonmetal mine safety and health—who enforce the law through a system of district, subdistrict, and field offices located in various states.

Coal Mine Safety and Health Districts' Areas of Jurisdiction and Office Locations

District 1: Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Delaware, and eastern Pennsylvania. *District Office:* Wilkes-Barre, PA.

District 2: Western Pennsylvania. *District Office:* Pittsburgh, PA.

District 3: Maryland and northern West Virginia. *District Office:* Morgantown, WV.

District 4: Southern West Virginia. *District Office:* Mt. Hope, WV.

District 5: Virginia. *District Office:* Norton, VA.

District 6: Eastern Kentucky. *District Office:* Pikeville, KY.

District 7: North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Tennessee, Puerto Rico, Virgin Islands, and central Kentucky. *District Office:* Barboursville, KY.

District 8: Ohio, Indiana, Illinois, Michigan, Wisconsin, and Minnesota. *District Office:* Vincennes, IN.

District 9: Iowa, Missouri, Arkansas, Louisiana, Texas, Oklahoma, Kansas, Nebraska, South Dakota, North Dakota, Montana, Wyoming, Colorado, New Mexico, Arizona, Utah, Idaho, Washington, Oregon, Nevada, California, Alaska, and Hawaii. *District Office:* Denver, CO.

District 10: Western Kentucky. *District Office:* Madisonville, KY.

Metal and Nonmetal Mine Safety and Health Districts' Areas of Jurisdiction and Office Locations:

Northeastern District: Maine, New Hampshire, Vermont, Massachusetts, Connecticut, Rhode Island, New York, New Jersey, Pennsylvania, West Virginia, Maryland, Delaware, Virginia, and the District of Columbia. *District Office:* Pittsburgh, PA.

Southeastern District: Kentucky, Tennessee, North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Puerto Rico, and the Virgin Islands. *District Office:* Birmingham, AL.

Table 1. Number of Injuries in Surface Mining, Injury-Incidence Rates per 200,000 Employee-Hours, Average Number of Workers, Employee-Hours, and Production, by Kind of Mineral Mined and Work Location, January-December, 1987*

	Bituminous Coal			Total surface mines
	Strip mines	Auger mines	Other surface mines	
Fatal	14	—	—	14
Fatal incidence rate	0.03	—	—	0.03

6.12.3 Health and Safety in Surface Mines

WESLEY G. JOHNSON

SURFACE MINE HAZARDS

Health and safety programs for any surface mine can be planned on the basis of recognition of hazards encountered in each activity of the mining process. In problem mines, statistics of severity and frequency of accidents can be used for program planning. Conditions will arise that are unique to a particular surface mine. Such conditions must be identified and safe solutions found, which, with training, will become part of the overall safe production process. In all cases continuous training by formal on-the-job, and by-example methods must be developed and used.

One measure of the seriousness of occupational hazards in surface mining is the number of fatalities caused by accidents. Another is the magnitude of NFDL—nonfatal with days lost—injuries.

First, based on statistics shown in Table 2 of Sec. 6.12.2, are the most severe accidents, ranked from the highest to the lowest according to the number of fatalities.

Powered Haulage

Accidents related to motion of powered haulage equipment. Included are accidents involving conveyors, front-end loaders, forklifts, shuttle cars, load-haul-dump units, locomotives, railroad cars, haulage trucks, pickups, automobiles, and personnel carriers.

Machinery

Accidents related to motion of the machinery. Included are all electric and air-powered tools and mining machinery such as drills, slushers, winches, draglines, power shovels, and compressors.

Exploding Vessels under Pressure

Accidents involved with bursting of air hoses, air tanks, hydraulic lines, hydraulic hoses, stand pipes, etc., due to internal pressure.

Explosives and Breaking Agents

Accidents involving the deterioration of manufacture explosives. Also in this category should be premature detonations caused by lightning or stray currents with electric detonators.

Fall of Face, Rib, Pillar, Side or Highwall

Accidents in this classification include falls of material while scaling down or placing retaining support and also slides or slumps of in-face material. Not included are acci-

dents in which the motion of machinery or haulage equipment caused the fall or slide either directly or by knocking out support.

Falling, Rolling, or Sliding Material

Accidents caused directly by falling material or other than material from the face or side; or, if material was set in motion by machinery, by haulage, by handtools, or while being handled or distributed, etc., the force that set the material in motion determines the classification. For example, where a rock was pushed over a high wall by a bulldozer and the rock hit another rock which hit and injured a worker, the accident is classified as machinery. Machinery (a bulldozer) most directly caused the resulting accident.

Next, based on available statistics (Table 2, Sec. 6.12.2) are the accidents that contribute most to the work days lost because of injuries.

Slips or Falls of Person

Accidents include slips or falls while getting on or off machinery and haulage equipment which is not moving, and slips while servicing or repairing equipment or machinery. Also included are slips and falls resulting from ice and snow.

Handling Material

Accidents related to handling packaged or loose material while lifting, pulling, pushing, or shoveling.

Machinery, Powered Haulage, and Hand Tools

Machinery and powered haulage are the same as defined earlier. Accidents classified in the hand tools category are those related to nonpowered tools.

Stepping or Kneeling on an Object

Accidents are classified in this category only when the object stepped or kneeled on contributed most directly to the accident.

Other

Accidents not classified elsewhere.

In mills, fatalities caused by the slip or fall of persons, electrical, handling material, powered haulage, and other accidents head the list of occupational hazards in surface milling operations of the United States.

Surface mine health and safety hazards listed in Table 1 and the notes following the table should be considered in planning and follow-up processes required for safe operation of any surface mine.

Table 1. Surface Mine Health and Safety Concerns

Function	Health and Safety Hazard or Concern	Detail No.
Mine Location		
Climate	Effects of cold, heat, or humidity	1
Light conditions	Visibility	2
Remoteness	Effects of boredom; stability of work force	3
Proximity to other workings	Effects of caving, slope failures; water inflow	4

Table 1. Surface Mine Health and Safety Concerns—Continued

Access roads and haulage ways	Separation from public roads; degree of curve, amount of grade, sight distance, condition of berms, markings	5
Water Control	Potential for subsurface and surface inflow; handling procedures, pumps, sumps, and pipelines	6
Ground Stability	Bank or highway design, potential for slope failure in waste or overburden coal or ore, tailing dumps, dams, and impoundment	7
Drilling and Blasting	Mobile equipment operating and maintenance procedure	8
	Explosives transportation, storage, and use procedures	9
	Fire safety	10
Mobile Equipment Operations	Mobile equipment operating and maintenance procedure (specific to individual types and sizes of equipment)	8
	Fire safety	10
Fixed Equipment Operations	Fixed and portable equipment operating and maintenance procedures (includes pumps, generators, and air compressors)	11
	Fire safety	10
Shop Operations	Mobile, fixed, and portable equipment operation and maintenance procedures	8,11
	Crane and hoist procedures	12
	Welding and cutting (gas and electric procedures)	13
	Shop tool and machine operating procedures	14
	Fire safety	10
Other Maintenance Operations	Fueling and lubrication procedure	15
	Tire maintenance procedure	16
	Fire safety	10
Mill Operations	Provision for protective guards, walkways, lighting, dust, noise, and fume suppression	17
Warehouse Operations	Forklift operations, lifting and carrying, slings and chockers	18
	Fire safety	10
Electrical Use and Distribution Facilities	Protection from contact, grounding, and flashover; fault protection and maintenance procedure	19
	Fire safety	10
Change, Toilet, and Lunch Room Facilities	Protection from transmission of disease, slips and falls, adequate facilities	20
		21
Employee Protection	Individual protective equipment including eyes	22
	Toxic dust and fume identification safety procedures	23
	Fire safety	10
	Slips and falls	21
	First aid, including emergency vehicle	24
	Alcohol and other drugs on and off the job	25
	Parking lots	26
	Driving to and from work	27

Detail 1—The hazard effects of cold, heat, and humidity on miners and equipment must be analyzed and prepared for. Personal protective equipment and special training may be required. At mines where large ranges occur, special facilities and equipment may be required. Mobile equipment must be outfitted with heaters and air conditioners. Operating conditions will change as freezing or thawing occurs. Inflows of water may vary widely, requiring special training for all personnel.

Detail 2—Light conditions may vary from long days with strong sunlight, requiring eye protection, to long black nights requiring glare-proof lighting.

Detail 3—For the individual, boredom affects safety; for society, increasing mine remoteness reduces hazards associated with contamination of water supplies by mining, flooding through failure of dams, etc., dust, and noise. (Individually, miners must be protected from adverse effects of dust, noise, and exposure to toxic materials.)

Detail 4—Slope stability must be maintained to protect miners and equipment. In addition to pit walls and

Table 1. Surface Mine Health and Safety Concerns—Continued

spoil banks, slope stability includes design and construction of drainage structures, truck dumps, roads and ramps, or any excavation or builtup earth structure with walls (slopes) of natural materials.

Design of slopes hinges on engineering, geologic, and hydrologic factors associated with the rock mass. Usually as steep a slope angle as possible is sought for economic reasons (reduction of waste to ore ratio, for instance). Pitted against the steep slope angle are consideration of safety and economic loss (injury and property damage). Economic considerations include equipment damage and possible disruption of mining sequences.

Detail 5—In order to eliminate hazards associated with public use of mine roads or vice versa, all mine access and haul roads should be totally closed to public use. (Public action and the attendant liability is uncontrollable; hence no access is required.)

Design of mine roads must match the needs of the largest vehicle using the road, including degree of curve, superelevation, sight distance, placement and condition of berms and guard rails (which are usually useless for haulage units), traffic plan, and marking and illumination.

Status of road maintenance, dust suppression activities, adherence to traffic rules, and vehicle condition are continuous safety concerns.

Detail 6—Review of plans for water control (both surface runoff and pit drainage) may reveal hazards. Work systems to carry out water control plans may reveal inadequate safety provisions for possible drowning; burial by slope failure; and injuries from installing and moving pumps, hoses, and pipelines. In low temperature areas special precautions are required. Pump crews require special training in prevention of electrical shock, burns, and fire during fueling operations. Proper lifting, carrying, and slips and falls protection must be taught.

Detail 7—Adequacy of slope or highwall design and adherence to design during mining should be monitored. Condition of such walls for dribble (rock and other material falling off walls), especially in areas where freeze-thaw occurs. Attitude of pit and highwall supervisory personnel regarding highwall safety may indicate training is required.

Provision for formal inspections of pit slope or highwall for indications of weakness are required. Waste or spoil areas are included. Impoundment dams and other water control structures must be monitored for signs of failure, in some cases as required by law (see MSHA regulations).

Detail 8—Mobile equipment operating and maintenance procedure: involves task training to insure operator knowledge or operation of controls, warning devices, and safety features. Observation and grading of operation expertise by competent authority, with periodic update to insure highest quality of operation. Training includes understanding of operating principles of mechanical and electrical components and fire safety.

Such equipment includes: draglines, bucket wheel excavators, cross pit conveyors, shovels, special excavators, haulage trucks, tractor scrapers, truck tractors, wheel tractors, front-end loaders (articulated and conventional), motor graders, backhoes (excavators), blasthole and exploration drills, conventional trucks, and special equipment such as water distributors, cable movers and reel vehicles, tire changer vehicles, compactors, ripper attachments, cranes, hoists, and forklifts, all types of farm equipment, and pumps (gasoline, diesel, and electric).

Detail 9—Surface mines consume considerable quantities of explosives which are controlled vigorously by federal and state agencies through laws and regulations. The following federal agencies control explosives used in mining: *Dept. of Commerce*: Interstate transportation of explosives; *Dept. of Transportation*: Transport on interstate highways (most explosives are delivered by truck); *Dept. of Treasury*: Bureau of Alcohol, Tobacco, and Firearms (BAF) licenses manufacturers, agents, and users of explosives. A mine is a user and requires a license; *Federal Bureau of Investigation (FBI)*: Investigates all thefts of explosive materials. Disappearance of explosives must be reported within 24 hr; *Dept. of Labor*: Mine Safety and Health Administration (MSHA). Controls safety in the storage, transportation, and use of explosives on mine property; *Dept. of the Interior*: Office of Surface Mining (OSM) controls protection of the environment from use of explosives at surface coal mines.

The best source of information regarding the subject of explosives is: Institute of Makers of Explosives (IME), 1575 I St. NW, Suite 950, Washington, DC 20005.

Detail 10—*Fire Safety*: Although widely acknowledged as important, fire protection often receives less than full support or attention. Continuous monitoring and training, including actual fire suppression drills, are worthwhile. Fire protection plans for facilities must be reviewed and adjusted to eliminate hazards. Fire suppression equipment, in addition to handheld extinguishers, may be warranted for installation on the expensive equipment at surface mines.

Modification of dust-suppression water trucks to include fire-fighting capability is worthwhile. Provisions for adequate storage and maintenance of water/fire trucks, plus training for operators, is required.

Safety inspections should include inquiry into fire protection adequacy for all parts of the mine.

A good source of information on fire protection is: National Fire Protection Association, 470 Atlantic, Boston, MA 02210.

Detail 11—Fixed equipment operating and maintenance procedure: involves task training and continuous update and monitoring of knowledge on operation, adjustment, repair, and fire safety of all fixed equipment such as cranes, fans, pumps, air compressors, fueling and lubrication devices, welders, electric motors, gear cases, crushers, feeders, and conveyors.

Detail 12—All mechanical equipment has individual operational characteristics which must be mastered to insure uniformly safe practice. Hoists and cranes require special care in that working conditions vary continually. Each load or pick is different, requiring experience for proper execution. Only rated or approved persons should operate cranes and hoists. Special training is required, especially in use of slings, boom angles, and outrigger (if used) placement. The Power Crane and Shovel Association is a good source of information (Milwaukee, WI).

Detail 13—Proper welding and cutting is an art that can be acquired only through training and practice. From a safety viewpoint, welding must be monitored to insure adequacy of safety training, including fire safety. Many fires are started by poor welding practice.

Detail 14—Formal training is required prior to operation of shop machine tools. A roster of qualified operators may be required to prevent injuries and damage to equipment. Ordinary tools require a common sense approach as do shop operations in general. The National Safety Council, Chicago, IL, has materials that may be of assistance for such training.

Detail 15—Fueling and lubrication procedure must be controlled to eliminate fire risks. Technical innovations such as the Wiggins Fast-Fuel System reduce dangers (and fuel loss). A safety check of the equipment can be made during the lubrication process.

Detail 16—Tire maintenance requires special training in the dangers involved, since extreme hazards exist. Inflation of mounted tires must follow a prescribed routine. Task training with periodic update is necessary, with observation of tire work monitored by supervisors and safety inspectors.

Detail 17—Mill or process plant operations contain potential hazards mainly associated with fixed and mobile machinery and equipment. Regulations address these hazards in general, such as machine guarding; walkways; handrails and toeboards; protection from noise, dust, and toxic fumes; and adequacy of lighting. Other hazards will exist, depending upon the process being used such as electrical, flame or heat, and explosive atmosphere dangers.

Conduct of repair work creates special hazards requiring foolproof lock-out procedures, adequate scaffolding and ladders, and lifting devices.

Supervisory and safety inspection attention, with continuous training, is necessary.

Detail 18—Warehouse operations contain specific hazards associated with fork lift equipment and falls of

Table 1. Surface Mine Health and Safety Concerns—Continued

stacked or piled materials. Lifting and carrying techniques must be monitored and updated through training. Lifting devices, including hoists and cranes, require specifically trained operators.

Dangers of fire and explosion may exist, requiring attention to housecleaning.

Detail 19—Electrical safety in surface mines requires constant attention. Because of the expanded use of high voltages (up to 25,000 V), much of the energy used is distributed by ground-laid cables which are exposed to damage in numerous ways (fly rock from blasting, equipment rock spills, and damage from being driven over). Moving these cables has become a daily activity which must be monitored carefully to insure safe practices. Proper equipment must be used in order that the cable is not damaged internally by too small bending radius or excessive tension loads when dragging it.

Detail 20—Protection from transmission of disease may vary to some extent according to climate. Precautions in regard to drinking water and foodstuff consumed at the mine are necessary. Availability of bathing facilities, clothes lockers, and toilet facilities is mandated by regulation. Housekeeping of such facilities must be provided for and monitored by supervisors and mine health and safety personnel.

Detail 21—Slips and falls account for many injuries in surface mines. The workforce attention to hazardous conditions in regard to slips and falls must be obtained by continuous training. Access to equipment by operators requires proper use of handholds and safety steps. Proper footwear and safety belts may be required. Continuous attention to walkways, ladders, scaffolds, and manlifts is required.

Detail 22—Certain personal protective equipment is required by regulation, such as protective footwear (steel-toe boots), hard hats, eye protection (depending upon hazards such as welding, grinding, and chipping), special gloves for electric cable handling, and filter masks. Many surface mines require, in addition, safety glasses (including sunglasses) welder protective clothing, work gloves (for some jobs), tight (nonbaggy or loose) clothing, no jewelry, and tied-up hair.

Ear protection in the form of muffs and plugs is required for certain jobs. Much of this equipment may be provided to each miner, including in some cases insulated lunch and water containers, protective clothing for mechanics, and hardhat liners for cold climates.

Detail 23—Use of toxic materials centers in processing mills. Continuous monitoring of chemical materials used will control hazards associated with miners' exposure to toxic materials. Particulate filter masks and positive ventilation of work areas will assist in resolving some of the hazards. Guidelines for control and use of toxic materials can be obtained from the National Institute of Safety and Health (NIOSH). A table of threshold limit values (TLV) will assist in checking the mine.

Detail 24—First aid training is required for all miners by regulation. Many mines have extended first aid provisions to include sponsorship of emergency medical technician (EMT) training for volunteer employees. EMT personnel can assist with annual first aid refresher training, are assigned as crew members for emergency vehicles, and contribute to the well being of the mine work force and surrounding community.

Detail 25—The use of alcohol and other drugs by employees is recognized as a source of potential hazards. Use on the job is not tolerated but carryover effects can produce disasters. Supervisory recognition of such effects and method of dealing with the situation requires careful handling to avoid a major personnel problem. Training for supervisors is suggested, with professional guidance in some cases.

Detail 26—Total commitment to mine safety requires concern for all aspects of employee safety. Parking lots can be unsafe areas which must be monitored. Mine equipment must not use employee parking facilities. Access and traffic flow are planned with safe sight distances and are well drained and lighted. In climates which warrant their use, electrical outlets are provided for engine heaters and snow removal is provided. Where conditions warrant, fences and control of entry are required, with no access to mine property by private vehicles.

Detail 27—Concern for mine safety provides a base from which miners will carry safety concepts over into their private lives. Training in defensive driving plus the daily practice of safe equipment operation will influence miners to become safer drivers on public highways. The awesome toll in so-called "accidents" on the highway can be improved through such training.

6.12.4 Health and Safety Organization

ARCHIE M. GILLISS

As has been discussed in the preceding pages, health and safety in surface mining begins with management's commitment to make it happen. As part of the production process, health and safety must be part of any planning involving the mine work force. This commitment must be evident in all levels of management to insure that the safety policy becomes part of all mine activity. The most logical starting point is at the top level.

A written policy is required stating top management's feeling toward company safety efforts and it should be displayed for each miner to see on a daily basis.

Health and safety controls are based on form of organization and management objectives. The following lists three types of health and safety organizations:

1. A separate health and safety organization, reporting directly to management, that oversees mine safety activity (a staff function).
2. A combined function organization where either employee relations or personnel departments oversee health and safety, and report to management (two-hat concept).
3. A separate department that reports to both the mine manager and upper level management. (Details of procedure and responsibility are carefully defined, as this is a line and staff organization.)

While there is no *best* organization, the last type is very effective.

Depending upon requirements, the training function can be established as part of the health and safety department. Safety personnel will conduct or arrange training, developing a strong relationship through contact with mine personnel.

The need for training is often misunderstood and sometimes confused with the need for job performance evaluation, a production and safety department function. When performed, training must be done in a manner that reflects a positive safety attitude.

Statements like, "We've got a training problem because our workers aren't safety conscious," or "He really must change his attitude. . .," are often listed as the problem when it is merely a symptom of the problem. The training function must work closely with the safety function if it is a separate department. The difference between what is being done and what is supposed to be done in the job can be termed as a "performance discrepancy." The method used to correct such a discrepancy may not be training; however, working with the safety and production departments, performance may be changed through positive and, in some instances, negative reinforcement.

HEALTH AND SAFETY PERSONNEL ACTIVITIES

The basic function is one of service to the mine operating department. This philosophy is carried out by inspecting and observing safety practices and assisting mine management in correcting deficiencies. Potential health hazards are detected and solutions suggested, but, in all cases, mine management is responsible for health and safety matters. Specifically, the following services are rendered:

- 1) Conducting periodic health and safety inspections to insure compliance with company and regulatory agencies, with formal reports.

- 2) Assisting in correction of deficiencies.
- 3) Organizing and conducting safety and other training; maintaining training records.
- 4) Investigating all accidents; issuing formal reports.
- 5) Maintaining statistical records of accidents and health records and periodically reporting status.
- 6) Interfacing with regulatory safety agencies as required.
- 7) Planning emergency procedures for fires, storms, and other catastrophes, and conducting drills.
- 8) Researching improvements for all hazardous procedures.
- 9) Functioning as a health and safety information source for mine personnel.
- 10) Extending influence to off-the-job health and safety.
- 11) Develop improved ways to reduce injury, accident, and work environment costs.

HEALTH ITEMS REQUIRING ATTENTION

Specific health items for surface miners must be monitored as required by law. These items involve the work environment of each miner and any potential injury, hygienic, or disease situation which might arise:

- 1) Exposure limit to noise: maximum allowable, 8 hr 90 dBA, 15 min 115 dBA.
- 2) Exposure limit to dust: 2 mg/m³ (coal) [includes threshold limit values (TLV)] limits for a long list of toxic materials as set by the American Conference of Governmental Industrial Hygienists].
- 3) Skin irritations caused by chemicals, lubricants, cleaning solutions, and various fumes.
- 4) Adequate illumination.
- 5) Protection for eyesight.
- 6) Potable drinking water.
- 7) Adequate number and cleanliness of sanitary facilities (shower and toilet facilities).
- 8) Adequate ventilation, including positive fume removal from welding and cutting operations.
- 9) Monitoring of correct use and storage of carcinogenic and radioactive materials.
- 10) Monitoring of exposure to excessive heat or cold.
- 11) Continuous review of fire safety conditions.

PRINCIPLES USED: ACCIDENT PREVENTION EFFORTS

There are no quick remedies or gimmicks that can improve a safety record or performance. It is sticking to basic principles and using basic philosophy that has been developed and perfected throughout the years by professionals that will improve safety performance. General industry concepts are perfectly acceptable in coal mining and vice versa. In the long run, positive results will follow.

Basic principles are guidelines that broadly describe what has to be done to have an effective accident prevention program. The *how to* details are different in each application. Using ingenuity, imagination, and past history data, effective programs can be developed that are basic, but workable.

The foundation for accident prevention is the establishment of a cause or causes of accidents and eliminating same.

Accidents are caused by an interaction of people, equipment, material, and environment. Two very basic components of this are *unsafe practices or acts* and *unsafe conditions*. Of the two, unsafe conditions are the simplest to control. Changing unsafe practices is more of a challenge, as this portion deals with the human factor. The only way to prevent unsafe practices is to eliminate their causes. Going back to the basic foundation means finding the cause and eliminating that cause. This is the elimination of such causes as:

- 1) Inadequate job skills.
- 2) Lack of knowledge.
- 3) Lack of incentive to perform work safely.
- 4) Physical and mental limitations.
- 5) Motivations that conflict with working safely.
- 6) Lack of job procedures.

The basic way to eliminate unsafe conditions is to correct the condition and the cause of the condition.

M. U. Eninger (Eninger, 1981) lists 16 essential principles that outline a program of what needs to be done to prevent or eliminate unsafe practices and unsafe conditions. A listing of these 16 (ten associated with unsafe practices and six with unsafe conditions) follows:

Principles for eliminating unsafe practices:

- 1) Provide an overall safety orientation to new employees before they start to work.
- 2) Provide an occupation safety orientation to employees moving into new occupations.
- 3) Develop standard written job procedures for known hazardous jobs in each occupation.
- 4) Develop and publish general safety rules that cover the most probable and serious unsafe policies.
- 5) Provide thorough initial job safety training to employees who have moved into a new occupation, using job training guides when available.
- 6) Check job safety training with planned follow-up safety observations.
- 7) Conduct a program of regular, planned safety contacts to maintain employee awareness of hazards and precautions.
- 8) Always reinstruct employees observed working unsafely. Never walk away from an unsafe practice.
- 9) Provide prejob instructions to employees assigned to do infrequently done, high hazard jobs.
- 10) When possible, pair off inexperienced employees with experienced employees who can share their job safety know-how.

Principles for eliminating unsafe conditions are as follows:

- 1) Where supervision has authority to order correction, prompt correction of unsafe conditions should be ordered.
- 2) Where such authority is lacking, the unsafe condition should be reported to higher supervision, together with recommendations for corrective action.
- 3) Where supervision has authority to correct the source cause, the correction at the source should be ordered or taken.
- 4) Where such authority is lacking, the source cause(s) should be reported to higher supervision, together with recommendations for corrective actions.
- 5) When correction of an unsafe condition necessitates delay, supervision should take whatever temporary precautions are necessary to reduce the hazard.
- 6) Supervision should always follow up to be sure that correction ordered or requested has been applied.

A review of these 16 items or principles will show very little change in accident prevention concepts since the early 1960s.

Regardless of the industry or the business establishment,

the role of management in any safety program takes precedence over any of the other elements. Where the responsibility for preventing accidents and providing healthful work environment is pushed off to the safety department or safety committee, any reduction in the accident rate is pure coincidence. Every member of the management team must have a role in the safety program. This thought is not new, but it is seldom employed.

A careful review of a successful safety program will show an involvement at all levels of management. Employee involvement in the safety program will also be very evident.

In today's environment, the same management principles and concepts that are applied to quality, cost, purchasing, and production must also be applied to safety. If most safety programs were examined, the results would show that the same management techniques being used to solve production problems are not being used to solve safety problems. Production problems are being left to line management, safety problems are handled by the safety department.

Management can hardly be expected to fulfill various safety functions that take even a little additional time unless they see a good reason or a need to do so. Past practices may have been to let the safety department handle safety, and they have gotten by. Hence, the number one job in mining is to teach or convince management that safety is a good practice of a good manager. As has been stated throughout this subsection, every successful safety program starts from the top of the organization and works down. The company president or mine manager passes the responsibility down through the ranks of management to the first line supervisor. However, in doing so, each level retains a participation part in the program. The first line supervisor now becomes the focal point. It is there that the program either dies or flourishes. Supervisors must be convinced that the sincere efforts they make to prevent any type of accident will cause their employees to rapidly accept safety leadership. Poor examples will destroy a program. In a sense, a good safety program that is built around the supervisor is a cornerstone of good employee relations.

There are many benefits other than a reduction in accident rates when a good safety program is achieved. Lower turnover, less absenteeism, steadier work, and improved morale are a few of these benefits.

Safety and health are just as much a part of a worker's job as productivity. The key is accountability. Once accident prevention procedures have been written and responsibilities defined, individual employees should be held accountable for successful implementation. Standards identifying responsibility areas for each management level need to be set. The responsibilities, as listed, then provide the managers with basic requirements on which they can develop their own specific responsibilities.

In safety it is not enough to have good intentions, but all employees must recognize the good work and efforts that are put forward.

WORK FORCE INVOLVEMENT

Health and safety input from the work force is basic in maintaining a safe mine. Formal recognition of this can be made through assignment of safety duties to miners in all parts of the mine. In some cases, safety committees are established through company efforts that suggest health and safety improvements. Committee members may accompany MSHA inspectors (as required by law) on formal inspections. Some companies prefer to have individual miners participate

in all inspections, including both those conducted by the company safety person and MSHA inspectors.

Details of good safety practice are discussed openly during the course of inspections. Proposed changes in operations are reviewed to determine if such changes truly improve safety or if some other aspect needs to be altered. Possibly no facility change is required, but change in operator method or attitude is determined to be best. Such communication, later documented as a course of action with management approval, is fundamental in order to achieve a no-accident status at any mine.

Accident investigation data produced during the investigation process should be reviewed with all individuals involved or who possibly could be involved in the work process.

HEALTH AND SAFETY ORGANIZATIONS

The following organizations play important roles in surface mine health and safety. Due to the evolving nature of the subject, additional information may be available.

Society of Mining Engineers, Inc.

Mine Safety and Health Administration, US Dept. of Labor

National Safety Council

American Society of Safety Engineers

American Institute of Governmental Industrial Hygienists

Certified Safety Professional Organization

National Fire Protection Association

American National Standards Institute (National Electrical Safety Code)

Holmes Safety Association

6.13 Communications and Controls

R. C. VOIGE

INTRODUCTION

Communication and control systems provide a vital link in a surface mine operation. The interaction of operating personnel through various types of communication instruments and the similar control of equipment through telemetry instruments is essential to a well-run operation. In recent years computers located on mobile machinery have also used radio communication to transfer digital data between the mobile units and fixed base stations.

The major use of communication and control systems at surface mines is productivity and safety-related. Telephones and mobile radios enable operating personnel to change plans instantly and have these plans carried out at remote locations. Also, the status of mining equipment can be monitored continuously and preventative maintenance initiated at the first sign of a malfunction. Computer-aided dispatch systems using a mobile radio can maximize the use of haulage vehicles. The safety of blasting operations is improved by the use of special warning signals over communication systems. Equipment operators who are performing a potentially hazardous task alone have mobile radios to contact rescue personnel in case of an emergency.

There are four general types of communication and control systems in use at surface mines today. They are:

Wired Voice Systems (telephone, public address, intercom)

Mobile Voice Systems (two-way radio, paging)

Wired Monitoring and Control Systems (telemetry, remote equipment activation, equipment and machine monitoring)

Mobile Monitoring and Control Systems (vehicular telemetry and location, shovel and dragline telemetry, remote equipment activation)

WIRED VOICE SYSTEMS

The most widely used wired voice system is the telephone. Telephones provide basic communication throughout the mine property and tie into public systems. High reliability and simple operation have been the cornerstone of telephone operation in the United States. Microprocessor technology has been incorporated into automatic switchboard design, producing features such as call waiting, call forwarding, automatic call back, and call transfer that make telephone communication more productive.

Wiring for telephone systems consists of lines to each instrument and trunk lines to the local public telephone exchange. The automatic or, in some cases, manual switchboard is the hub of the system. Each telephone instrument must have at least one pair of wires connected to it and instruments with push-button line selection require a pair of wires for each "line." A telephone wire plant (wire and cable system) for a mine will include an appropriate number of 6- and 12-pair cables from small groups of phones that feed into local junction boxes. Then larger 25-, 50-, and 100-pair cables complete the circuit path to the centrally located switchboard equipment. Terrain, climate, and other factors will determine whether aerial or buried cable is used to connect remote locations.

A second type of wired communication system is the public address system. Large open areas such as the warehouse and shop can be equipped with a high-powered am-

plifier (25 to 200 W) and multiple speakers to provide communication to roving personnel. Audio systems have one outstanding advantage over telephone systems in that, with a high-powered amplifier, a paging call can be heard over and above the high ambient noise conditions found at a surface mining operation. Telephones or intercom stations are used to respond to the audio page.

An intercom system usually consists of a number of stations that have low-power amplifiers (0.5 to 3 W) and built-in microphones. Remote stations are selected by use of a simple switch. A multi-pair cable to each station is required for this low-cost type of system.

MOBILE VOICE SYSTEMS

Mobile communication is now accepted as the best way to contact surface mining personnel who are usually found in vehicles or on foot throughout the mine property. The basic components of a mobile communication system are an antenna, transmitter-receiver, microphone, speaker, and power supply. The vehicular transceiver (transmitter-receiver) is usually mounted in some out-of-the-way place in a car, shovel, truck, or locomotive. A microphone and speaker are mounted inside the vehicle (or cab) for the convenient use of the operator or driver. The antenna will be mounted high on the vehicle or at a safe location to minimize breakage. Most surface mine systems will also use an a-c-powered base station radio with an antenna tower.

Mobile communication can help reduce a surface mine's capital requirements. Fewer road trucks, fewer switching locomotives, fewer loaders and material handling tractors, are needed to attain productivity goals when their operators can be directed by mobile communication. Fewer clock hours and man-hours are needed. Fewer people are needed to perform many tasks; mobile communication can be instrumental in the transformation of waiting and idle times into working time. When a man and a machine finish a task at one part of the mine, mobile communication can instantly direct them to another part of the mine for another task. Without such a tool, management would have to hire another man and buy another machine. Employees who are physically alone are never out of touch when their supervisors, subordinates, and peers can reach them by mobile communication.

Mobile communication is an exchange of information between two or more parties who are free to walk, run, or drive in separate directions as they communicate with each other. The medium is usually a two-way radio, so called because each instrument can transmit and receive. But in day-to-day business, many mobile communications turn out to be the multiway radio, in which several mobile parties transmit to each other. In certain two-way radios, the speaker is silent until a transmitted tone or digital signal opens the receiver to the sender's message. There are selective two-way systems that activate a small group of receivers out of a population of many. There are selective one-way systems, reaching a single pocket-size radio pager with an audible tone or a tone-and-voice message.

A radiotelephone uses a duplex system, that is, both parties can talk and/or listen at the same time. Most two-way mobile systems are simplex, with a push-to-talk button on the microphone. At each unit, pushing the button activates

the microphone and transmitter while shutting off the receiver and speaker. Releasing the button reverses the condition; the operator can now listen. The push-to-talk arrangement conserves power, since the receiver's consumption is much less than that of the transmitter.

Communication can be in the form of a voice message or at times a data message between terminals.

The mobile communication of business (including mining) is carried out principally on frequency modulation (FM) radio, on frequencies which the Federal Communications Commission (FCC) limits to certain classes of users. For example, there are sets of frequencies for public safety, manufacturing, construction, agriculture, forestry, trucking, railroads, utilities, petroleum producers, and, of course, miners. The FCC must restrict not only the allocation of frequencies but also the radios' transmitting power to minimize interference and give access to as many legitimate users as possible.

Mobile communication is normally of limited range: within the plant, within the property, within the city or county. But the communication is not necessarily direct from radio to radio. In some systems, a two-way radio will transmit to a repeater, a radio which automatically re-transmits the message—at higher power—to other two-way radios in the system.

Mobile communication, then, increases the ability of management to manage its mobile people. It should be noted that mobile communication is not an electronic tether. It cannot prevent wandering of mind or body; it cannot prevent inefficiency. But, in the hands of motivated people and organizations, mobile communication is invaluable. It brings mobile minds together; it increases the value of each mind, the productivity of each person, and the return on the organization's investment in its people and property.

Heinrich Hertz produced radio waves in 1888. It occurred to Guglielmo Marconi that such waves could be used in communication. He demonstrated the mobile radio in 1898 by following the Kingstown Regatta in a tug and flashing the results to the office of a Dublin newspaper. A radio SOS brought aid to the crew of a sinking lightship in 1899, to the passengers of the distressed steamship *Republic* in 1909, and to the passengers of the *Titanic* in 1912. But the idea of radio communication from a conveyance smaller than a ship was not immediately pursued.

The first broadcast-band automobile radios were installed in the late 1920s, followed by the first police department radios in the early 1930s. An FM radio pioneer, Daniel Noble, found that FM was more reliable than AM (amplitude modulation) in mobile communication, and he developed a two-way system for the Connecticut state police. During World War II, the walkie-talkie military two-way radio was said to have been the most essential piece of communication equipment in the Battle of Normandy and the subsequent invasion of Europe. After World War II, the way was clear for the production of FM two-way radios for police, taxi, and transportation users.

Subsequent developments, in the 1950s, included a car telephone, complete with a dial, to interconnect with telephone-company lines, the pocket paging receiver, and the widespread use of transistors.

In the 1960s, new manufacturing techniques improved the stability and reliability of the mobile equipment. By replacing the old vacuum tubes with solid-state devices (principally transistors), manufacturers were able to reduce the size and weight of their units. They were able to make compact multichannel radios and to develop a mobile teleprinter,

which provided hard-copy readout in a vehicle. Later printers also had keyboards for data entry.

In the 1970s, there was a sizable growth in the mobile communication of digital data and in the use of integrated circuits and microprocessors in such sophisticated products as the portable handheld radiotelephone.

Table 1 is a list of FCC classifications of service. There is wide-spread use of mobile communication in business and government. A fuller list of mobile communicators would, at least, include the federal and state governments, all utilities, the public transit system, and such industries as airline, marine transportation, telephone, mining, and construction. But while applicability would seem to be infinite, the portion of the radio spectrum available for mobile communication is finite.

Land mobile communication takes place at 25 to 50 MHz (low band), 132 to 174 MHz (high band, otherwise known as very high frequency or VHF), 403 to 430, and 450 to 512 MHz (ultrahigh frequency or UHF). During the 1970s, the band from 806 to 870 MHz was allocated to mobile radio users.

The low band is widely used by mining, county, and state law enforcement units, long-haul truck and bus lines, pipeline operators, electric and gas utilities, and other organizations that require long-range mobile communication. Low-band range may be as high as 80 km (50 miles) in flat terrain, less in hilly terrain. But it has a disadvantage in skip interference, in which a user's transmission skips far beyond its normal range. Low-band systems on opposite coasts of the United States have been known to cause mutual interference.

The high band is used by those whose operations are generally within a limited area. Range may vary from 8 to 64 km (5 to 40 miles), although greater ranges are often experienced.

The UHF band is ideal for short-range surface mining communication. It provides a clear two-way radio link.

The following is an overview of the capabilities of mobile communications equipment: the mobile and personal two-way radio, radio repeaters, radio pagers and paging encoders, monitors, control centers, and base stations.

Mobile Two-Way Radio

A unit designed for vehicular installation is called a mobile radio. The microphone, with its push-to-talk button, is shaped to fit the hand. A coiled cord connects the microphone to the control head, containing the on-off, volume, frequency selection, and squelch controls. A simple squelch circuit minimizes the reception of noise when no one is transmitting. A more sophisticated squelch circuit keeps the speaker silent

Table 1. FCC Service Classifications

*These services are available for use in mining activities.

until a brief sequence of inaudible tones opens the circuit and lets the message through. Typically, the user's transmitter begins each transmission with the tone sequence that opens the squelch circuits in that user's vehicles only. A more advanced system is digital squelch, which uses digital codes instead of tone codes. In the most economical FM two-way mobile radios, the control head, transmitter, receiver, and speaker are all in a single housing. In the more common configuration, the transmitter and receiver are in a separate, locked case, installed under a seat or in the trunk; the speaker also is separate from the control head. This allows room for the components that provide particularly high power (within FCC-mandated limits), high selectivity (reducing adjacent channel interference), low distortion, and clear audio output. It also allows room for the various optional functions. In addition to the squelch, they may include:

Busy Indicator: A light goes on when the frequency is being used by other people. Without a busy indicator, the user of a vehicular two-way radio has to monitor the frequency, that is, open the squelch circuit and listen, before transmitting, to be sure the frequency is not being used. When a driver transmits without monitoring his frequency, he may obliterate parts of another user's message. If the obliterated message concerns a life-or-death emergency, such carelessness may have a fatal consequence.

Transmit Timer: Another possible problem can be the inadvertent keying of the transmitter in the vehicle. The microphone may have been put into place carelessly, jamming the button and causing the errant transmitter to interfere with all two-way radios in the system. As a solution, the unit may have a timer, which shuts off the transmitter after a predetermined period.

Selective Signaling Codes: The "party-line" aspect of mobile communication has its disadvantages. Hearing every two-way communication, all day, may increase a driver's fatigue and make him less sensitive to his own messages. And, in many operations, one driver's job is of no concern to another.

The solution is selective signaling. It enables a base station operator to contact a single driver or a group of drivers. Various tone codes or digital codes act as keys that unlock certain receivers, either individually or in groups. The user thereby combines the mobility of radio with a degree of address exclusivity. And if a driver happens to be out of his vehicle when a selectively signaled call comes in, a "call received" light on the decoder's panel stays on until the driver removes his microphone from its hang-up box. Some selective signaling equipment will sound a vehicle's horn, briefly, or turn on the headlights as a reminder that a call has come in.

Scanning Monitor: This function sequentially samples each channel of a multi-channel system, and stops automatically when it detects the presence of a carrier or a message. One channel is designated as the priority receive channel, and if that channel receives a signal during a scan, the receiver automatically reverts to it.

Radio Paging: A radio pager is a compact radio receiver that emits an alerting signal when a unique tone-code activates the receiver's tone-sensing circuitry. A *tone-only pager* emits a signal only; a *tone-and-voice* pager allows a voice to follow the signal. Most pagers are about the size of a cigarette package and weigh 170 g (6 oz) or less.

Many two-way radio users have radio paging as part of their own communication systems. Pressing a series of buttons at the control center will signal a single pager. The

operator can signal a group of pagers, or all the pagers, in systems that have group-call or fleet-call capability.

It may have a push-to-listen button; the user hears the voice message only if he pushes the button. It may be able to receive a page without sending an alert; later, pushing a button will retrieve the stored signal. Or the signal may come through immediately, not as an audible tone but as a vibration; this is useful when the user is in a conference or in a noisy area. Or the pager may be capable of a tone that is either pulsating (say, a signal to call the office) or steady (a signal to call home). From an array of paging products, the user can find the unit that fits his working style and environment.

A monitor is a pager that enables the listener to hear his own tone-and-voice message and, by flipping a switch, to monitor all conversation on the frequencies. They may be used by mines, for example, to carry tornado and blizzard warnings.

The earliest mobile two-way radios had vacuum tubes, which had to be mechanically cooled and which failed frequently. The latest units are 100% solid state, that is, free of moving parts, heated filaments, or vacuum gaps. Some are resistant to dust, shock, and vibration and are so weatherproof that they can be mounted outside the vehicle. The earliest units required crystals to establish their transmitting frequency. Many still do. But in the state-of-the-art mobile two-way radios, the crystal has been replaced by an electronic frequency synthesizer. To change or add frequencies, the user replaces the memory module of the radio's microprocessor control system.

For many years, 5 ppm was the standard of mobile transmitter stability. The synthesizer's stability is 2 ppm—a significant improvement in the transmission of voice and particularly in the transmission of data.

Portable Two-Way Radio

Today's radios bring mobile communication wherever a person can go. A person has complete freedom of movement—and yet he is never alone, never without direction, never without access to authority, to assistance, and to the full resources of his organization. To a user of portable two-way radio, weight is no problem: a multifrequency radio with battery and digital squelch may weigh less than 0.7 kg (1½ lb). Some recharge in as little as 1 hr; some are designed and approved by MSHA; some give their operators a choice of four frequency channels with the turn of a single knob; some allow them to communicate on as many as eight frequencies. Some are available with noise-canceling headsets, allowing the user to speak and listen with his portable in extremely noisy areas. At least one model slips into and out of a case mounted under a dashboard. When the user is in his vehicle, he has a true mobile radio, complete with a mobile microphone, speaker, antenna, and a connection to the automobile battery. When he is about to leave the vehicle, he takes out the portable, which instantly becomes a self-contained, two-way communication device.

Repeaters

Low-power mobiles, portables, and base stations can operate in a system that requires communication over a wide area, even an area containing hills and valleys. The system makes use of radio repeaters, sensitive receivers which pick up weak signals and feed them to transmitters, which repeat them at higher power.

In many areas, a repeater is at the top of a hill or mountain. It picks up signals from several users and retransmits them at the users' assigned frequencies. A user's base station

may be connected to a rooftop dish antenna, which beams the signal at the repeater antenna many miles away. A rooftop antenna is advantageous because FM transmission takes a line-of-sight path; it does not follow the earth's curvature as AM transmission does.

Base Stations

These are the nonmobile transmitting/receiving radios through which management or its representatives communicate with people in the field. A base station may be self-contained in a desktop cabinet, complete with controls and a microphone connection. Or the base station may be a remote-control model; a control console and the microphones or desk sets may be elsewhere. Some base station systems have telephonelike desk sets with push-to-talk buttons instead of a microphone and speaker. The base station may be local/remote: operated during the day as a local-control station and during the night, as a remote-control station accessible by ordinary wireline telephone from a management person's home, which would also have a control console. Or, as a combination base station and repeater, it would transmit/receive for the base units and repeat for the field units.

Control Consoles

These control the more complex base station functions. While a simple control station, a desktop unit may determine the receive/transmit, squelch, and frequency selection; a floor-based control console contains an array of controls.

Most consoles have a modular design, which makes customization economical. Various switch panels may fit into various console bays and cabinets which, when assembled, comprise a control center. In this way, the center can grow with the organization. A fully equipped console may have vehicle status indicators, an illuminated map, a system of spotting lights (to spot the vehicles' positions on the map), a paging encoder, tape recorders, an intercom station, and more.

WIRED MONITORING AND CONTROL SYSTEMS

Surface mines have used hard-wired monitoring and control systems for a variety of applications including pumps and valves. Simple audio frequency (tone) systems and more complex digital systems utilizing FSK (frequency shift keying) are used to transmit information to and from remote locations.

An example of this use follows. The water level in a holding pond has risen to a critical level because of failure of the main pump. A monitoring system would pick up a signal from a water-level sensor and indicate this problem on an annunciator panel in the mine office. An auxiliary pump at the pond can then be manually or automatically started by a control system from the mine office.

In recent years, microcomputers have expanded the use of monitoring on draglines, shovels, front-end loaders, and other mobile mining equipment. A basic system would include a microprocessor to process data from various sensors and to drive an operator's display. Additional memory, display capability, sensors, and hard copy reports are optional features. In addition the microprocessor, an analog to the digital processor, monitors the voltage and current levels of the hoist, drag/crowd, and swing motors on a dragline or shovel monitor. Synchro encoders are used on the hoist and drag/crowd drums and swing gear to sense bucket position.

The microprocessor monitors the various machine parameters and gives the operator the option of displaying appropriate parameters during each machine cycle. Table 2 lists typical operator display parameters. Table 3 lists typical

operator warnings that are programmed into the microprocessor. This real-time performance information is very useful in improving dragline productivity.

On-board computers are also being used to monitor operating parameters of haulage and loading vehicles. Engine, drivetrain, hydraulic, and lubrication system failures are displayed for the operator. Performance data can be stored and then retrieved for periodic maintenance.

MOBILE MONITORING AND CONTROL SYSTEMS

Most of the monitoring and control functions described in the previous section on wired systems can also be performed using radios as the link. Truck operating and warning parameters can be combined with an automatic vehicle identification system.

Data communication gives the mobile user direct access to the memory of a distant computer. And it gives management an up-to-the-minute report of its mobile units' activity and productivity.

A maintenance man, for example, can enter the equipment model number and get a full alphanumeric display of information from the computer on parts, service notes, or other information to help in the maintenance of the equipment.

A typical mobile keyboard display terminal may provide a 240-character message display in a 6 × 40 format, for example, and may have an alphanumeric keyboard and several functional keys. It sends and receives through the vehicle's mobile radio and the system's base station. To and from the base station, the data flows through a mobile com-

munication processor, a central processing unit, and the system's control console. A mobile communication processor controls all the functions required to encode, decode, check, and correct messages in a mobile data terminal system. It transforms outbound messages from digital to analog and inbound from analog to digital.

In the vehicle, an alternative to the complete mobile terminal is a status-message terminal. It has several push-buttons, each of which sends an abbreviated routine message that gives the vehicle's status and helps the dispatcher manage the fleet. In a haulage system, for example, such messages might include *loading*, *enroute to site*, *waiting*, *discharging*, and *empty*. The system saves time for the driver and dispatcher; it gives management up-to-the-minute information on material flow; and it makes the briefest possible use of the channel.

Radio communication of data is also being used in haulage truck dispatching. When a truck passes a radio signpost—a roadside transmitter designed as part of the system—the signpost transmits its location digitally to the truck's mobile radio unit, which repeats the information (along with digital identification) in a message to the base station. The data then flows through a mobile communication processor to the central processing unit. With that information and a

special software package, the computer is able to dispatch a haul truck fleet efficiently. Through the use of a computer making millions of calculations to determine the proper dispatching sequence, substantial savings can be obtained. It is estimated that a significant portion of the total cost in running a fleet of haul trucks can be saved.

The system will also monitor truck parameters such as low on fuel, low on oil pressure, high on engine temperature, and other readings, all with automatic vehicle identification.

Data communications can also be used to control and monitor remote location. It can be used to monitor a water tank and to turn the pump on when the tank gets low or it can be used to monitor a pond's level and sound an alarm if it is in danger of overflowing.

Data communications by radio can be used for communications between man and man, man and machine, man and computer, computer and machine.

SUMMARY

The use of electronic equipment for communication, monitoring, and control at surface mines is increasing each year. New applications for radio and computer equipment will continue to improve both productivity and safety.

6.14 Productivity

MICHAEL B. KAHLE

INTRODUCTION

Productivity is a simple idea that is often complex to measure and to apply in public or private policy—but it is vital to our performance. In the past century, rising productivity has been the source of higher living standards through wages and benefits that increased much faster than prices, the source of shorter hours of work, more leisure and longer life expectancy, and the source of enhanced public goods such as education and public health. Rapidly rising productivity acts as partial long-term antidote to inflation.

During the last 10,000 years, man has made dramatic improvements in his productivity. Usually this improvement has occurred through larger or more efficient equipment, along with improvements in labor relations and better resource evaluation. The last 50 years has seen tremendous growth in equipment size and technology. This growth started with the steam engine and moved through the eras of the internal combustion engine and the electric motor. Larger and larger horsepower units provided higher-capacity excavating and haulage systems. Growth will continue in this area but probably not at the pace previously experienced.

The other element of productivity that has seen changes over the last five decades is the workforce. In earlier generations, workers were ruled by security needs. A good job was one that paid the bills and kept the family together, but times have changed. The notion of a full employment economy, increased education and sophistication, and richness of support programs for the unemployed have raised our workers to a new plateau. They now insist that work provide not only security but, equally important, heavy doses of recognition, meaning, and growth, all of which can affect worker productivity.

The third element of the productivity equation is the better understanding and utilization of our natural resources. It has not been until the last decade that this element has demonstrated its importance to productivity. Due to the greater capital need for mining and the escalating cost of mining operations, a greater emphasis will be placed on mine planning. This planning will include a greater use of geostatistics to evaluate reserves and plan mine production and more sophisticated computer applications in mine production monitoring and evaluation.

RESOURCE PRODUCTIVITY

Mine Planning

Planning for productivity is a continuing activity which begins with the initial pit design and continues throughout the mine life. Sound decisions made in the initial pit and plant layout will pay back dividends in terms of productivity for many years, while poor ones will come back to haunt the operations. The annual preparation of long-range forecasts offers the planner an opportunity to modify the operating plan to take into account changing economic conditions, new mining techniques, more productive equipment, etc. The periodic short-range forecasts direct the daily mine operations, making the most productive use of existing

equipment and personnel while staying within the parameters of the long-range plan.

Pit Planning: The techniques used to develop the geologic model have been discussed in an earlier chapter. The end product of the resource modeling is a computer model made up of uniformly sized blocks of material. The block size is selected after considering the mining bench height, the structure and mineralization detail, the exploration drill hole spacing, the anticipated mining methods and equipment sizes, and the limitations imposed by practical data processing. Each block has a defined spatial location within the model and contains ore grades, mineralogy, and rock type required for resource evaluation. Estimates of the metal prices, metallurgical recoveries, and mining and milling costs provide data for the dollar evaluation of the resource. Sound engineering judgment of the following factors will greatly influence the economics of the final design and the productivity of the proposed pit:

1. Haul road location, widths, and grade.
2. Pit slopes, as determined by rock type structures, water, slope height, and road location.
3. Location of the ore and waste material within the pit.
4. Utility access.
5. Crusher and mill location.
6. Dump location.

Forecasting: Long-range forecasts, or schedules, are prepared annually to cover various periods of time or through mine life. The preparation of the forecast includes calculation of stripping ratios, blending of ores from different mine areas, estimation of tons remaining, and provides the basis for the preparation of long- and short-range budgets. The computerized mine plan together with a computer program that simulates the mining of the resource has greatly reduced the drudgery of this work and has allowed more time for the examination of different options, such as reading mill feeds, changing ore cutoffs, or blending tonnages from different pushbacks. The end result is a permanent record on maps or a computer list of the benches or partial benches that will be mined each year with the corresponding ore grades. This record can be compared to the actual mining at the end of the year and discrepancies between actual results and forecasts can be explained if need be. Upon completion of the long-range forecast, historical data on productivities and costs can be used to determine the equipment, manpower, and dollars needed to produce the forecast tons and the long-range budget is completed. Here again, computerized financial programs can be used to produce the budget along with sensitivities and probabilities of the plan.

Short-range forecasts are prepared as needed at the individual mine. They can be made as simple or as complex as needed and are primarily used to guide the operations for a given period of time to assure an orderly development of the long-range plan, a continuous supply of ore, and a uniform mill feed. A detailed four-week forecast would be laid out on copies of the bench maps showing the weekly areas to be mined by each shovel and/or loader. The size of the areas shown will be determined by the productivity of that particular machine and by the tons needed to produce a desired blend of ore. Upon completion, the forecast is pre-

sented to the operations and maintenance personnel and their input is encouraged. These discussions often result in modification of the forecast for one reason or another, but the end result is a smooth-running mine and an orderly development of the longer-range plan.

Operational Data: The need for accurate operational data becomes apparent in the preparation of the long-range and short-range forecasts and budgets. A few years ago, the amount of information that was accumulated was proportional to manpower available to record it. Today, computers have simplified this chore and accumulate, process, and deliver more data in the desired format.

Production data and the associated operating hours are recorded and accumulated by shift, day, month, and year for each loader, shovel, drill, and truck; tonnages mined are totaled by bench and pushback; ore tonnages hauled to various discard dumps are recorded also. Other information can be added when needed, such as haulage distances, tonnages into and out of stockpiles, and tonnages mined outside of plan. The computer output of this data can be expressed in many ways; however, the planner is most interested in the equipment productivities expressed in tons per shift.

The source of the data to be recorded is usually available from reports filed by the shift foremen or from time cards turned in by employees at the end of the shift. This data is only as reliable as the source and, in some cases such as truck haulage records, human errors can result in poor data. To prevent this and to expand the data available on pit haulage, haulage truck monitoring systems have been developed.

Computer dispatching of haulage trucks is currently being used in open pit mines around the world. The primary benefits are increasing effective truck utilizations between 10 and 15%, eliminating material going to the wrong destination, improvement of pit activity reporting, and providing a more consistent flow of material to the concentrator. Current trends are to improve the usage of dispatching to blend complex ores, and to couple dispatching systems with on-board monitoring of truck functions, such as engine compression, wheel motor amperage, and tire temperature. Computer dispatching coupled with trolley assisted truck haulage has the long-range potential of evolving into driverless trucks. The US Bureau of Mines is currently evaluating human monitoring systems, developed for the military, for continually testing driver alertness throughout the shift. This, too, would be coupled with dispatching systems.

Miniaturization and ruggedization of solid-state electronic components, together with advances in computer technology and radio communications hardware, now facilitates sophisticated on-board monitoring of mining and materials handling equipment. As industry's acceptance of on-board monitoring increases, the technology will probably evolve to automation and finally robotize. Hence, on-board computerized monitoring is a significant development which will ultimately change the way new mines are operated, staffed, and managed.

Mine operators and equipment manufacturers in Australia, South Africa, Germany, Sweden, Canada, and the United States are active in automating and computerizing processes within the mining/materials handling sequence. Materials transport, formerly dominated by truck haulage, is being automated with conveyor systems and computerized by truck dispatching. Productivity of conventional excavation equipment, such as shovels and draglines, is being increased by monitoring performance with microprocessors and providing a real time feedback to the operators.

In general, the on-board monitoring systems provide the following:

1. Log and summary report of key operating parameters.
2. Automatic detection of the excavation/haulage cycles so performance statistics can be presented on a per cycle basis.
3. Visual display of performance data.
4. Chronological log of operating times, delays, and alarms.
5. Shift reports.
6. Operator feedback display.
7. Maintenance monitoring.
8. Simple diagnostics.
9. Operator interaction with the microprocessor.

Some of the issues which should be considered in selecting and using on-board computer systems are:

1. The number of input data ports.
2. The ruggedness and simplicity of the hardware.
3. Redundancy of critical functions.
4. System flexibility and ease of field modifications.
5. Filtration and isolation of input signals from each other and from radio signals.
6. Compatibility with existing radio communications systems.
7. Standardization of hardware components.
8. Compatibility with mainframe computing facilities.
9. Provisions for routine maintenance.

The present trend toward automation and computerization of mining processes is expected to continue. Future manpower requirements for a mining operation are anticipated to emphasize the maintenance functions rather than the operating functions.

Maintenance Planning

Computers are used in a variety of maintenance applications from scheduling preventative maintenance (PM) inspections to reporting operating costs. PMs and cost analysis did not evolve from the computer, but rather the computer was applied to these areas because it easily and accurately handles the information manipulation necessary for such programs. This results in a more accurate, up-to-date data base for maintenance planners to work from.

The basis of a solid computerized maintenance system is the gathering and reporting of operating information; operating hours, repair hours, and labor and supply costs. Accurate up-to-date information insures accurate computerized programs.

Preventative Maintenance: Preventative maintenance programs aim to discover maintenance problems before they become serious enough to disrupt production or damage equipment. Once identified, the repairs can be scheduled to minimize production delays and maximize maintenance labor utilization. Instead of equipment breaking down during production and repair crews being summoned immediately on an emergency basis, the equipment can be scheduled down, its production capability replaced by other equipment, and men scheduled for the repair. This is a productive use of men and equipment.

The computer easily controls a PM program by using operating hours to calculate the time remaining on the PM cycle. For example, haul trucks can be called in every 200 hr, shovels every 300, and support equipment every 250 hr. The computer even identifies the specific routine to be followed. The payoff for any PM program is great, since studies have shown that increased PM activities result in increased

equipment availability and a more productive maintenance force, hence more productivity through scheduling.

The computer can easily take PM scheduling one level further, by scheduling PM activities on components. The computer knows on which piece of equipment the component is located, and takes the proper operating hours when calculating the PM inspection cycle time remaining. Imagine tracking components by hand.

Predictive Maintenance: Predictive maintenance is a variation on the PM theme: predict the life of a component. A component's life is determined and the computer gathers operating hours against that expected life. As the remaining expected life shortens, the component is flagged for attention. The component's replacement can be scheduled to minimize production delays and maximize the maintenance workforce productivity. Engines and wheel motors are prime candidates for this, as their replacement involves days of downtime, many manhours, and thousands of hours.

On-Board Component Monitoring: Computers are being used (in conjunction with computerized truck dispatch systems) to monitor components on-board. Several components have benchmark values assigned to them in the computer and each time a truck is interrogated, the component values are reported to the computer. The computer then checks the value against the benchmark and examines the variance. An excessive variance can be flagged. Examples of components easy to monitor are engine oil temperature and pressure, wheel motor oil temperature, and wheel motor cooling air flow.

Quality and Performance Monitoring: Computers can increase productivity by the timely reporting of performance and quality. For example, fuel consumption indicates performance. Engine rebuild life expectancy vs. actual hours indicates quality. A computer can quickly and accurately track many such factors. Repair history can be computerized for fast query and retrieval to identify equipment failure trends that may indicate poor replacement parts or repair procedures. Equipment availability calculations and utilization figures indicate the performance of equipment and maintenance programs. Again, timely accurate information allows a more productive management of the resources.

Oil Analysis Program: Oil is usually sampled in conjunction with the PM inspection. The oil is analyzed by computerized equipment that translates the reading into meaningful values. These values are compared to acceptable values and tracked for either an unacceptably high value or a trend of differential, final drive, wheel motors, and hydraulic systems of all-haul glycol, fuel dilution, viscosity, and for certain metals, such as aluminum, copper, lead, iron, silicon, chromium, silver, tin, and nickel. If the presence of any of these exceed the manufacturer's guidelines, the machine is called into the garage and the problem corrected.

Electronic Analysis: For smaller equipment such as pickups and light trucks, electronic engine analyzers are used to diagnose mechanical problems and speed up repairs. For haul trucks, a load box center performs the same diagnostic service. With it, the electrical system of a diesel-electric haul truck can be tested by putting the system under simulated loads while the truck is stationary.

Tires: Tires are tracked by computer as to their location and life. Hours to failure and mode of failure are reported on and studied for trends that may mean tire manufacturing problems or operating procedure problems. Tire location is also tracked for tire rotation. New tires are mounted on the front, run there for approximately 200 hr, and then rotated to the rear. The computer does this tracking effortlessly. Tires

removed from a truck, but with tread remaining, are cataloged by the computer so that they can be matched with similar tires for mounting.

Cost Monitoring: Everything revolves around costs. If there is a system that accurately reports costs in a timely fashion, timely cost reduction decisions can be made. Some of the areas where computers enhance cost reporting are determining unit costs per piece of equipment and unit costs per component. This gives a measure of when the equipment is no longer economical. It can identify how much each component costs, allowing comparisons between pieces of equipment. If these reports are tied to trend analysis, problems can sometimes be identified before they become serious. Detailed costs analysis allows you to study the feasibility of sending repairs out, test new materials, identify areas for new procedures (different ways to line buckets), or just watch the results of cost reduction decisions.

EQUIPMENT PRODUCTIVITY

Over the past century, surface mining has changed from a predominately rail haulage system to its present truck haulage method. The needs of large scale open-pit development have been met with the larger capacity machines which in turn, need faster, larger, and heavier mobile equipment for materials transport. But ever-greater tonnages, increased energy costs, inflation, and longer hauling distances from larger and deeper pits are making truck haulage an economic question mark. Present and future surface mining operations are now contemplating a major increase in the use of conveyor belts. Conveyors are viewed as a way to slow rising fuel and labor costs at surface mines.

Excavators

Draglines: To improve productivity, US surface mines have relied on larger and larger stripping machines. This trend, however, has been tapering off as planning techniques become more sophisticated to get the most of the equipment on hand. As operators are forced to cope with increasing overburden depths, machine cycle times are longer, thus reducing machine productivity. Operating factors are being critically examined and simulated by operators and include maximum allowable suspended load, bucket selection to suit overburden conditions, strip profiles, boom angles and lengths to determine maximum operating dump radius, ballasting, and maintenance delays.

Several firms have developed dragline production simulator computer models. The model can simulate months or years of mining in minutes. Early results of the simulator tests on actual mining operations reportedly have achieved a 16.5% increase in production.

Shovels: Shovel productivity, tons per hour, is determined by dipper size, swing time, truck box size, and truck spotting conditions, as shown in the following equation:

$$\text{ton/hr} = \frac{\text{truck box m}^3 \text{ (cu yd)}}{\text{shovel dipper m}^3 \text{ (cu yd)}} \times \frac{\text{shovel swing time}}{\text{truck spot time}} \times \frac{\text{truck box t (st)}}{\text{t (st)}}$$

The shovel swing time is determined by the machine operating characteristics, material type, and swing arc to the truck. The spot time factor normally varies between truck-shovel configuration and single or double spot loading conditions. Table 1 presents representative cost and productivity data for a wide range of electric shovel sizes.

Table 1. Electric Shovel Data

Shovel size, m ³ (cu yd)	Capital cost, \$ *	Operating Maintenance cost, \$/hr [†]	Metric tons (st) per hr
6 (8)	1,000,000	40-80	725-1100 (800-1200)
9 (12)	1,300,000	40-110	900-1600 (1000-1800)
11 (15)	1,500,000	40-140	900-2040 (1000-2250)
15 (20)	2,100,000	40-140	1100-2720 (1200-3000)
19 (25)	3,000,000	40-140	1100-3400 (1200-3750)

* Includes freight, sales tax, and erection charges.

† Includes direct labor, operating supplies, lubrication, electric power, teeth and adaptors, hoist cables, and maintenance costs.

The introduction of the larger 23 m³ (30 cu yd) class shovel has recently provided an improvement in excavator productivity. As the improved operating economies led to greater unit production, the 23 m³ (30 cu yd) electric mining shovel is used more often in today's shovel/truck operations. Mine planners find its larger size cost-effective because they can specify fewer benches—this larger shovel can handle bank heights from 12 to 15 m (40 to 50 ft) only. Moreover, operations management recognizes the 23 m³ (30 cu yd) shovel's inherently greater production capability—it can load in three to four passes the large 154-t (170-st) (and larger) trucks currently available.

Realizing the 23 m³ (30 cu yd) shovel's mine value, both because of its cost-effectiveness and larger capital investment, manufacturers have taken steps to optimize the productivity and reliability of this shovel size.

Among the steps taken were the following:

1. Incorporate proven and new design techniques which increase the excavator's reliability.
2. Achieve long life for machinery and structures.
3. Improve maneuverability for faster shovel positioning.
4. Reduce maintenance and improve performance of electrics.
5. Employ large-capacity, wide-front dippers for better fill factors.

Loaders: In the past, loaders have not had the power to challenge rope-operated shovels. Now they do. In addition, larger unit sizes [15 m³ (20 cu yd)] in recent years have allowed hydraulic loaders, with their improved mobility, high selectivity, and use in a wider range of applications, to achieve higher productivity. Two new methods for loading trucks faster, at reduced production costs and higher productivity, have been devised. The new methods, staggered tandem and chain loading, reduce truck loading time, not haulage time.

Using staggered tandem loading, one loader and possibly, a second, dumps into the truck before it backs into place against the loading face. This reduces the time for one truck to pull out and another to back in for loading, thus increasing truck productivity.

The second method, chain loading, requires a loader for each bucket load needed to fill the truck. The loaders line up along the loading face and move straight in and out from the face. The truck passes between the face and the loaders

and stops underneath the raised bucket of each loader to receive a bucket load. Chain loading reportedly took 12 sec to load a 77-t (85-st) truck vs. 1 min to get a truckload with the conventional tandem method.

Trucks

Truck Effectiveness: Haulage truck productivity is generally assessed in terms of tons per hour, based on a payload carried per trip, times the trips per hour. Because of the variables involved, estimating truck productivity is probably the most complex portion of haulage truck evaluation. Computerized simulator programs have been developed to assist the miners in evaluating truck productivity. These programs contain the dipper and swing times for various excavators as well as performance and braking curves, dump, spot and delay times, box capacity, speed limits, and rolling resistance for haulage trucks. Table 2 shows typical output.

The key data are the simulated cycle time and the tons per hour. The potential effect of truck size on shovel productivity can be noted in the table and serves as a valuable operating management tool.

Trolley Trucks: Trucks with trolley assist remain an area of interest to US surface operators. Rapidly increasing diesel fuel costs can provide trolley assist as an economically attractive alternative. Reports indicate that using a 136-t (150-st) truck, predictions show a 9% increase in productivity gain and a 31% decrease in operating cost. Studies indicate that trolley assist performs best with grades greater than 5% and should be considered relatively permanent installation.

Sishen-Saldanha Irai Ore Project in South Africa is a good example of the success of the trolley truck method. When the conversion is complete, there will be 66, 150-wt trucks converted for use on eight overhead trolley assist lines. Results to date show a system that has reduced fuel consumption 30 to 40%, shortened haulage cycle time, and is expected to significantly reduce motor wear. When a fully loaded truck going up an 8% grade engages the overhead line, it can nearly double its speed, typically accelerating from 12 to 22 kW/hr.

Computer Dispatching: Computer-based truck dispatching has proved a production improvement to system over previous conventional voice radio based manual/visual dis-

Table 2. Haulage Truck and Shovel Effectiveness Report Shovel-Truck Assignment Sheet

Bank cond	Op. hr available shovels	Time trucks	Spot conditions	Truck fleet	Load capability	Cycle time	Per truck		Per shovel		Trucks to assign

patch. Phelps Dodge Corp., Tyrone mine, has successfully used such a system. Productivity improvements associated with the dispatch system are a direct result of optimum route selection and a subsequent increase in productive operating time. The Tyrone mine has experienced a 14% improvement in productive operating time over the previously used radio dispatch method. In addition, secondary benefits included

less load misrouting and a generation of timely and accurate production reports. The productivity gains translate into an increase in production and/or a reduction in equipment requirements, resulting in substantial operating savings. Fig. 1 compares the equipment requirements of a dispatch truck fleet vs. a dedicated truck fleet using a computer-based dispatching system.

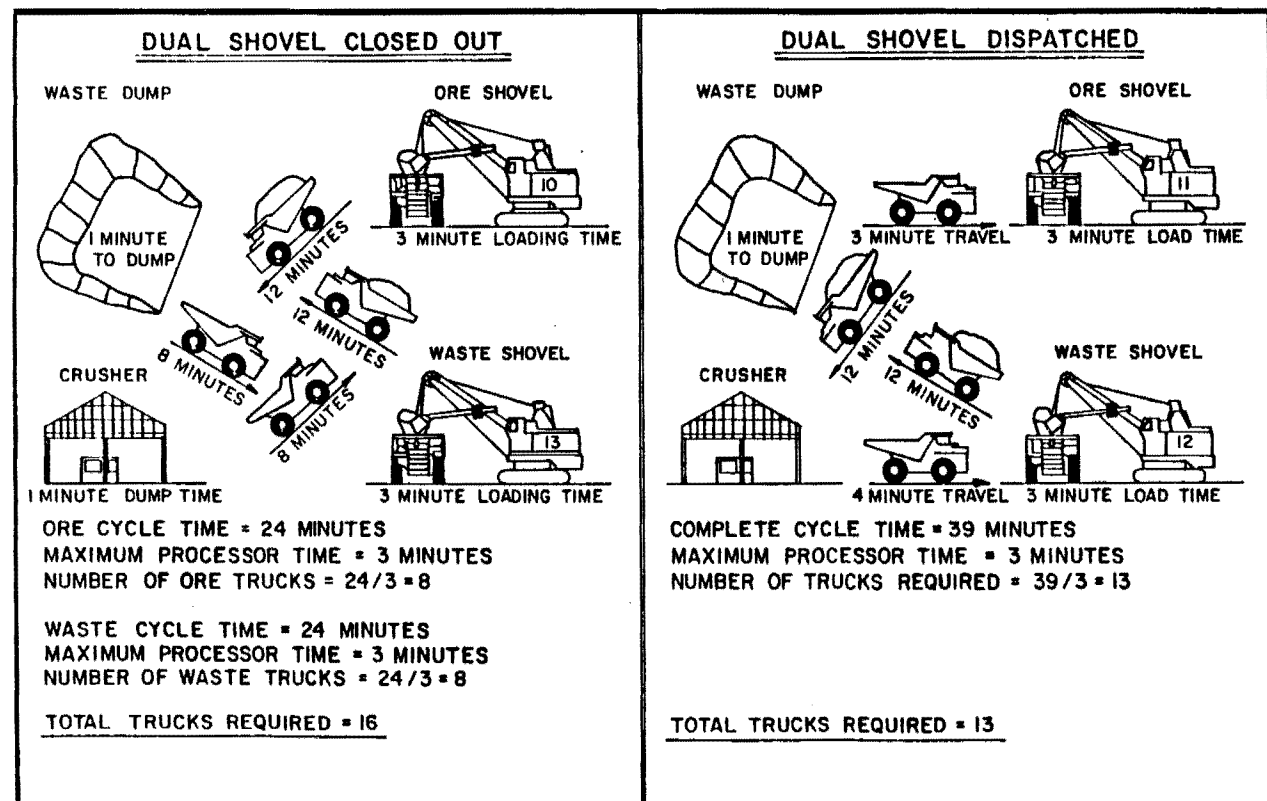

Fig. 1. Closed out (dedicated) vs. dispatched truck assignments.

Fig. 2. Movable concept with constant feed.

Conveyors and Mobile Crushers

As labor and fuel costs increase, and as open-pit and strip mines become larger, belt conveyors will become an important factor in holding down production costs and increasing productivity. There are generally three types of overland conveyor systems:

1. A movable source feeding a fixed terminal (bucket wheel excavator mines coal and conveys to plant).
2. Fixed source feeding fixed terminal (permanent crusher to plant).
3. Fixed source to movable terminal (permanent crusher to waste dump spreader).

Each of these systems has its problems. However, in every case, for distances up to several miles, a well designed and maintained belt conveyor system will prove to be more economical over a period of years and thus more productive than either truck or rail system. When conveyors are used in the pit, the long-range mining plan must be adapted to make the best use of the conveyor system's capabilities for increased productivity.

Usually, run-of-mine materials at most mines must be reduced in size before being transported by conveyors. Therefore, mobile or semi-mobile crushers offer one of the most effective available methods for in-pit conveyor systems. A mobile crusher is a completely self-contained unit mounted on a frame that is moved by means of a transport mechanism along the wall of the mine pit as mining progresses. The large primary crushers can be moved by setting the crusher

on a large frame which can be moved by tracks, wheels, or walking mechanisms. This portability promotes minimum haulage distances between shovels and the crusher by allowing the crusher to be placed at a location central to the shovels. The expense of the larger supporting structures and moving mechanisms is justified by their contribution to reduced fuel consumption and fewer haulage trucks and overall contribution to productivity levels. Fig. 2 shows an in-pit movable crusher-conveyor system.

LABOR PRODUCTIVITY

Productivity expresses a relationship between quantity of inputs—be it labor, materials, energy, capital, or some other aggregation—and the quantity of output. Output per man-hour, output per unit of capital, output per unit of energy, or output per unit of total input factors are all common measures; however, output per man-hour is the most frequently used or available measure. One of production's key components is a motivated, cohesive workforce that is dedicated to high standards of production and quality.

In earlier generations, workers were ruled by security needs; a good job was one that paid the bills and kept the family together. But times have changed; the notion of a full employment economy, increased education and sophistication, and a rich menu of support programs for the unemployed have raised workers to a new plateau. Workers now want not only security but, equally important, heavy doses of recognition, meaning, and growth.

In order that these expectations and demands be met and still achieve the required productivity, managers must recognize the legitimacy of the workers' search for self-esteem. Self-esteem has two interrelated aspects: self-confidence and self-respect. This is where good management becomes important. The modern manager must lead his workers into feelings of competence, involvement, and importance. A company can address such needs through better supervisor training and more direct worker involvement in the problems and activities of the workplace.

Management by Objectives

Management by objectives focuses on getting supervisors to commit themselves to meeting objectives. The objectives must be reasonable and attainable, but not necessarily easy. The objectives must be specifically documented and must be reviewed and updated routinely. The key word in this approach to better management planning is *accountability*. Employees will shirk responsibilities, but they will do what they are being held accountable for. In addition, employees need to know clearly their areas of accountability. This requires management to clearly communicate each employee's accountability.

Production Incentives

Production incentives are generally goal-oriented rather than oriented toward problem-solving. However, production incentives have proven useful in improving worker productivity. Generally, incentives are attractive once a company is pleased with its productivity and wants to push for a bit more. Incentives never should be used to attain an initial productivity goal.

Incentives can be a two-edged sword. If the goals are set too high, workers will become frustrated and can be a tremendous source of resentment. The royalty on each ton mined also cuts absenteeism, because workers do not get the bonus check when they miss work. However, management must be careful that the plan does not pay for what production should be achieving anyway.

Quality of Performance

An approach used to help a worker's personal efficacy and a sense of personal worth is that of quality circles. The quality circle techniques are familiar to approximately 1800 American companies and more recently have been introduced to the mining industry. The general purpose of the quality circle is to improve performance. Quality circles recognize that the people doing the work are most familiar with the problems that block their productivity on the job. The circles provide a mechanism for solving those problems that tend to demoralize and wear down employees.

A quality circle is usually made up of employees, both supervisor and workers, who volunteer to be in the circle. A foreman normally serves as the leader, but like other members, he has one vote in conducting circle business and decisions. The members of the circle are trained in brainstorming, cause-and-effect analysis, data collection techniques, graphs, and basic group dynamics. The circle group uses brainstorming to draw up a list of possible problems. Once a circle selects a problem, its first task is to gather data to discover the cost of the problem in terms of lost man-hours, wasted materials, downtime, or some other productivity measure. The circle group then uses its inherent knowledge to develop solutions and analyze the potential savings.

The circle will usually make a presentation to mine management proposing a solution. Each circle member participates in the presentation; the circle process is dynamic. Problems are routinely added by members, nonmembers, or management to the list of possible projects. Problems are often solved without formal circle action. Companies with the circles commonly find that problems will fall off the list because people are talking about problems and find that they can easily solve them themselves. The solutions are not presented to management because no expenditures or management action are involved.

Morale is a difficult attitude to measure. However, experience has shown that employees who are involved in solving workplace problems are more satisfied and generally more productive.

Mine Capital and Operating Costs

Robert F. Winkle, Editor

7.1 Introduction

When a mining property has been discovered, the exploration work completed, the feasibility studies and other planning activities finished, and the market analyses compiled, the ultimate go-no go decision depends on the capital required and the operating costs anticipated. Mining ventures and projects are undertaken with a view of gaining some benefit: earning a return to the stockholders for use of their funds (Jones, 1968). Net profitability is the bottom line.

Mining, as earlier chapters in this book will attest, is a complex undertaking with many variables (some of which are not under the control of corporate management) to be considered. First, the ore body itself will be a major factor in final capital expenditure decisions. For example, with a greater capital expenditure for a large plant, the deposit could be worked out in a shorter time span. Conversely, in order to maximize total profits, there would be an initial lower capital investment and a longer operational life for the deposit before it is finally depleted (Jones, 1968). Two other factors are the increasingly stringent environmental requirements imposed by governmental entities and the taxation treatment of mining profits from the aspects of depletion, depreciation, and investment credits.

From the late 1960s on, air and water pollution became a national conscience issue in the United States, with a proliferation of legislation, administrative agencies, comprehensive federal and state regulations, and a good deal of bombast in political campaigns, from the media, and by environmental groups such as the Sierra Club and Friends of the Earth. Although environmental concerns have had a greater impact on mining in the developed countries, recently such concerns have been surfacing even in such remote areas as Papua New Guinea (Tinsley, et al., 1985). The continuing stress on environmental regulation and control, needless to say, has its impact on capital and operating costs. For example, new smelter construction expenditures must include funds for extensive emission controls.

Space herein precludes coverage of the detailed economic and evaluation studies entailed in a capital expenditure decision, but numerous publications are available (Gentry and O'Neil, 1984; Jones, 1968; Stermole, 1987; Tinsley, et al., 1985).

Capital and operating costs vary with the commodity to be mined and the terrain in which it is located.

Iron Ore

Most surface operations are large scale and enormous quantities of ore and rock must be moved. However, much of the ore to be moved is dense and abrasive. Large equipment is indicated, but abrasive and corrosive aspects must be con-

sidered when maintenance costs are calculated. The section on iron ore that follows summarizes the basic philosophy, responsibilities, cost control methods, and equipment selection procedures that are applied in surface iron ore mining operations.

Coal

Surface coal mine capital and operating costs have not only been affected by the environmental control of air and water pollutants, but also by the increasingly stringent requirements for restoration of the land surface after mining ceases.

The costs of mining coal vary, depending on whether the operation is in the eastern or western United States.

In a section that follows, the costs of mining in a typical eastern coal mining state are delineated. Cost coverage begins with the permitting process, proceeds to engineering and construction, employment, equipment, other operating expenses, and concludes with taxes and fees. A case study of a West Virginia dragline operation, in a previous section, shows all the equipment considerations and statistical data that impact capital decisions and subsequent operating costs.

Costs of the unique mining conditions in the Powder River Basin of Wyoming in the western US are highlighted. The equipment to be used is a major capital factor and the philosophy entailed and the specific considerations involved in selection are discussed. Many variables are involved in these operations, such as personnel deployment, efficiency considerations, whether to contract or use in-company capabilities, scheduling, and the support structure needed.

Base Metals

The fundamentals of methods used to estimate mine capital and operating cost for base metal surface mine feasibility studies are detailed in the final section of this chapter. Since many of these operations are large scale, equipment requirements, selection, and operating costs are major factors in the capital decision-making process. Statistical data are given for each type of equipment that might be required in an operation. Numerical tabulations of initial capital expenditures and operation, replacement, and personnel requirements are provided.

From the commodity-oriented sections in this chapter, it is apparent that the process involved in making a capital investment decision is indeed a complex one. The many variables that pertain to a surface mine operation also affect operating costs once the decision has been made to put a

deposit/property into production. All of these analyses must be carefully and thoroughly done in order to achieve the final objective—a bottom-line net profit and return to the stockholders.

Metric equivalents: lt × 1.016 047 = t; st × 0.907 184 7 = t; in. × 25.4 = mm; cu yd × 0.764 554 9 = m³; ft × 0.3048 = m.

repair hours). There is a mathematical risk of lost production in basing the fleet size only on mechanical availability. For example, Table 2 shows that a fleet of 12 170-ton (154-t) trucks is needed to keep 9 operating on ore haulage. Referring to a random probability chart indicates that the probability of 9 of 12 operating 100% of the time is 96.64%. In other words, the risk of losing 3.36% of required production must be considered in determining whether the ore fleet will be 12 or 13 trucks.

Equipment Size and Type

Considering the large quantities of ore and rock involved, the mining equipment selected will be the largest available that will handle the tonnage, provide the required blend and operate at optimal cost. The cost is particularly important since to date the largest shovels, those above 13.8 m³ (18 cu yd), and trucks, those above 170 tons (154t) are unable to operate in the dense, abrasive iron ores at a reasonable maintenance cost. History indicates that these limits increase with experience.

The selection of a manufacturer to supply equipment requires objective evaluation. In general, all of the major suppliers can provide units which will perform adequately. The differences are in individual operating and maintenance items; therefore, the evaluation should be based on a comparison of common components and the selection based on the overall rating. A typical example for haulage trucks is presented in Table 3.

The system described is based on common practice and experience to provide a general guide to equipment selection. The planner should not restrict himself to the past—there is a great need for innovation in material handling. In any system, consideration must be given to technical advances

in computerization of pit design, fleet dispatching, and engine diagnosis and maintenance programs. In addition, items such as semi-portable primary crushers and screening plants, conveyors, electric truck assist, and blasting procedures are undergoing changes which will improve the efficiency of future mines.

Equipment Purchase Schedule

The schedule is based on quantities to be excavated. Crude ore requirements are usually constant while stripping varies with the depth, dip, and internal contamination of the ore body. The purchase schedule follows the annual mining and stripping requirements as determined from the reserve (life of deposit) mining plan. The fleet size will be minimal during preproduction stripping, increase to a maximum needed to maintain production plus a stripped ore inventory, and then decrease finally to the size required for production and the removal of internal rock.

Planned *high grading* or *selective mining* is a completely acceptable procedure to delay expenditures; unplanned is not. The key is to maintain production and to avoid a panic stripping program.

Contracting Out

Equipment used for stripping and mining is usually the same; therefore, the contracting out of either is not considered. By definition, miners are expert earth movers which makes a decision to contract stripping an admission of incompetence.

Preproduction stripping by the mine operator is a valuable break-in period for the work force and equipment. It should be fully utilized to develop the work habits of the team before the routine of normal operations commences.

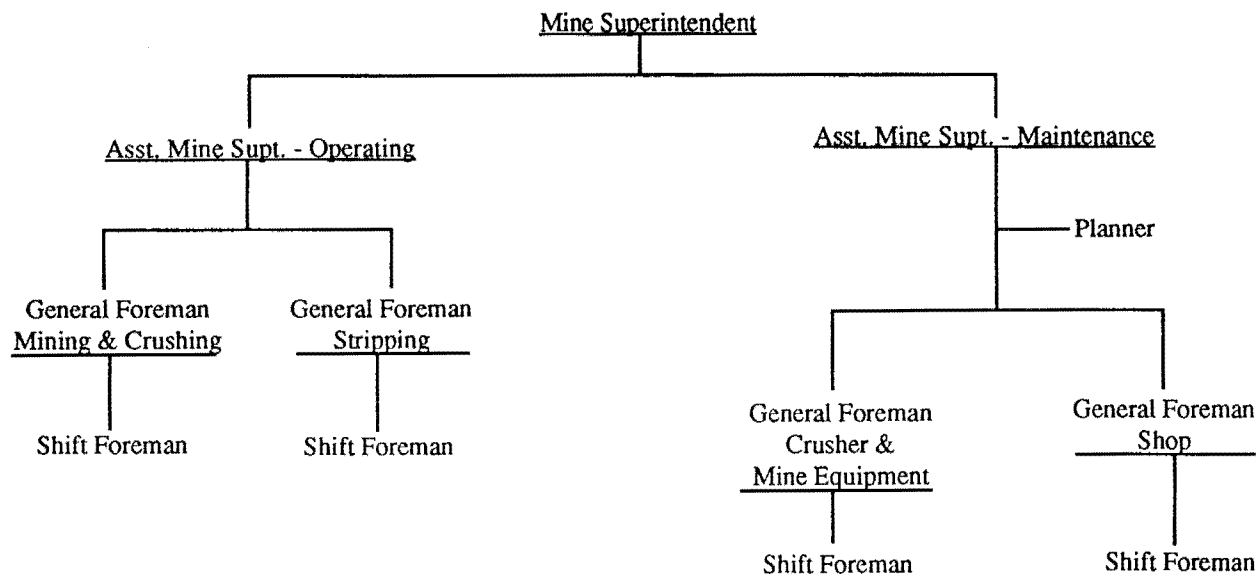

Fig. 1. Table of organization.

The contracting out of preproduction stripping should only be considered in these cases: (1) stripping by methods different from the mining method such as dredging, scrapers, or dragline; (2) stripping of quantities greater than will be required during normal operations.

TYPICAL OPERATING COSTS

Since this section deals with the mining portion of a total operation, the costs referred to are those under control of the mine superintendent. Comparing operations and operating costs is complicated because organizational responsibility and accounting methods vary greatly among mining companies. In this example, we assume that the mine superintendent is responsible for delivering crushed crude ore to the plant and that his table of organization is as shown in Fig. 1.

Budgetary responsibility follows organizational responsibility; therefore, the mine superintendent controls and is accountable for the items shown in Fig. 2. The superintendent is responsible for budgeting all items shown in Fig. 2. He is accountable for consumption of all supplies and labor and is entitled to a complete financial report.

This mining cost breakdown is not typical of a particular mining company; it is an example of the general areas of cost responsibilities. To pinpoint areas requiring attention, the mine superintendent requires detailed current and historical cost and performance data. With this information, he should be able to evaluate the relative influence of mining, stripping, and capital expenditures on his overall performance, and his overall performance to the profitability of the company. This management evaluation of all controllable costs is frequently neglected by:

Emphasizing production and production costs only.

Neglecting departmental influence on total performance, for instance, the potential increase in crushing and grinding costs by reduction of mining costs.

Cost control is a procedure used to generate profits; it should not restrict innovation or the utilization of changing technology.

The actual cost of producing a long ton of pellets in the Lake Superior-Canada areas varies from about \$21.00 to

\$26.00 f.o.b. minesite excluding stripping, royalties, depreciation, and taxes. It is important to note that the cost of transportation to the steel mills adds significantly to this cost, thereby eliminating many rich ore bodies from consideration until sometime in the future.

The major reasons for these cost variations are:

Size—Large operations have lower costs because fixed costs per unit of production are less. It is doubtful whether a new operation of less than 5 Mt/a (5,000,000 ltpy) would be seriously considered.

Weight Recovery—A difference of 1% influences the cost per long ton of pellets from \$0.45 to \$0.60.

Stripping—The advantages of a low stripping ratio are obvious as illustrated by the *all materials ratio* which is:

$$\frac{\text{Tons crude ore} + \text{tons rock stripping} + \text{tons surface stripping}}{\text{Tons pellets}}$$

Equipment—Modern, large, energy sensitive and computer or processor controlled equipment gives newer operations a significant cost advantage.

Table 4 illustrates the proportionate cost percentages for an average of seven North American taconite operations.

LEASING VS. PURCHASING

The initial investment required to build an iron ore plant is extremely high, about \$100 per annual ton; therefore, an operation is expected to last at least 25 years. The life of mining equipment such as drills, shovels, trucks, locomotives, rail cars, etc., has also increased due to the higher initial cost and to component replacement which enables the operator to maintain his fleet at much higher efficiencies than was possible in the past. In general, the only reason for changing equipment is to take advantage of new unit efficiency, technology, or to increase the unit size and this can be minimized by strict attention to the initial investment.

Leasing is a tool normally used to offset a current shortage of cash, or to obtain equipment for short term (10 years or less) projects. It should be remembered that the financial institutions which provide leasing services are also in business to make a profit. This adds to the fleet cost and usually

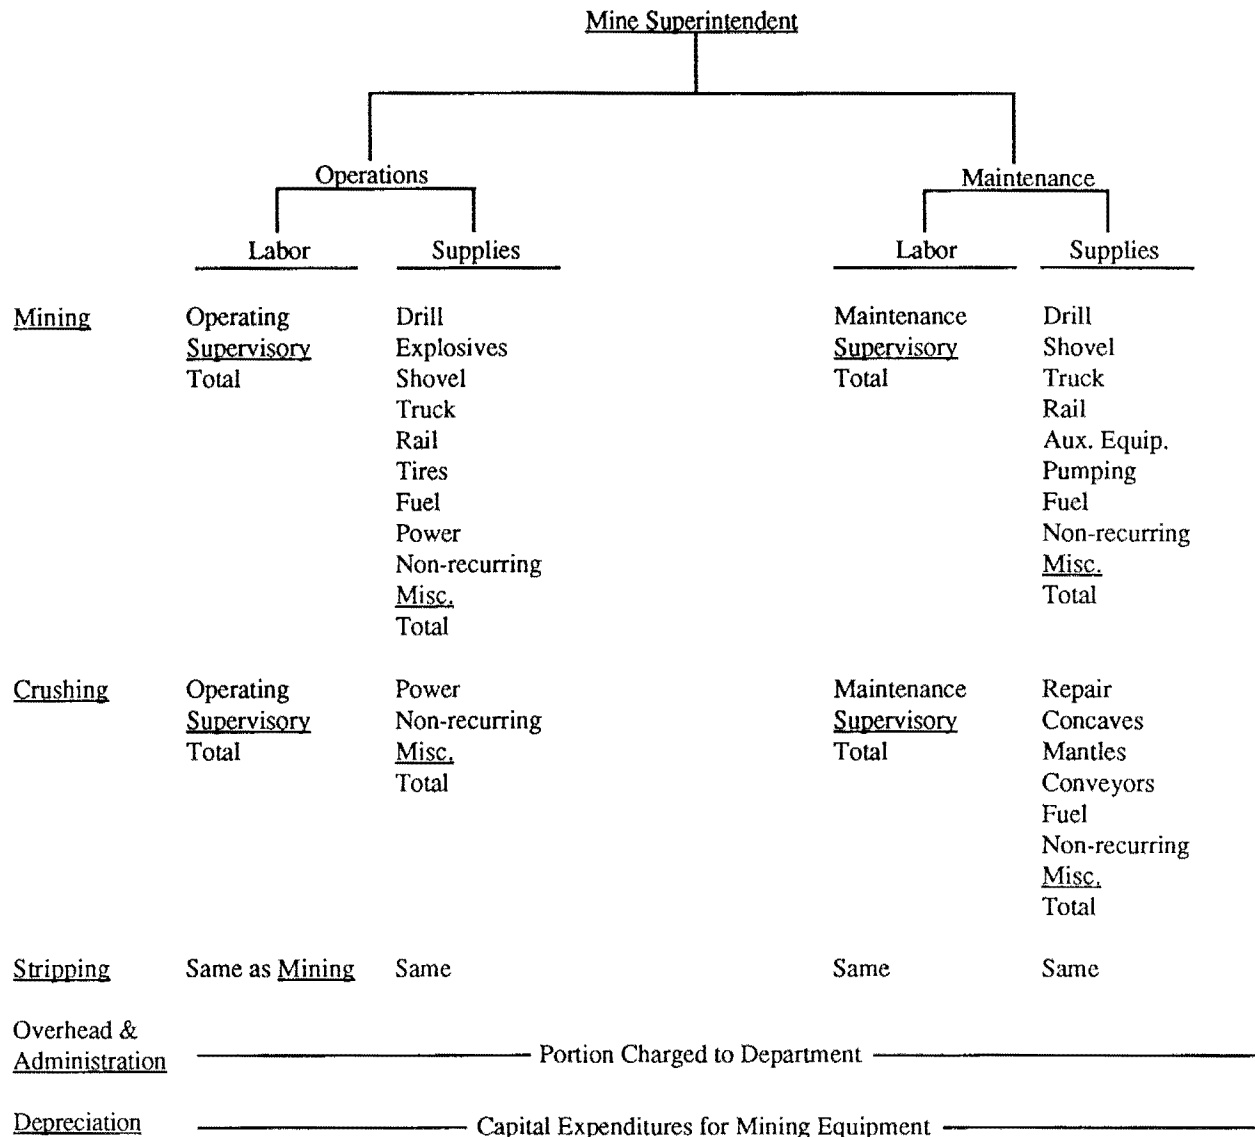

Fig. 2. Table of cost accountability.

results in a decision to purchase rather than lease, assuming cash is available. There may be advantageous exceptions to this depending on the tax laws prevalent at the time and in the area being considered. For instance, leasing can be attractive in a cash short situation when given the additional flexibility of either taking the investment tax credit (10%) or allowing the lessor (financial institution) to keep the tax credit. It is also important in evaluating a lease vs. purchase option to "present value" all lease costs at a consistent rate. However, recent history has proven that economic conditions and interest rates can vary significantly from time to time and, therefore, an evaluation in constant dollars must also be considered.

To illustrate the comparison of these various options, the following hypothetical example of the costs of obtaining a 170-ton (154-t) haulage truck is shown in Table 5. It should be noted that lease rates are subject to actual lending rates available at the time of equipment acquisition and there are many ways of approaching the leasing of capital equipment.

Balloon payments and guarantee residual values at termination used in this example are only two ways of demonstrating the use of the leasing tool that can reduce current operating costs and conserve cash flow. It is therefore essential that if leasing is a consideration, the purchasing and treasury departments be relied on to evaluate the lease proposals.

CAPITAL VS. OPERATING COSTS

Total operating costs cannot be significantly reduced by the expenditure of capital unless the expenditure is for a change in technology, a change in methods, increased equipment size, or improved efficiency. In other words, under given conditions (production, equipment size and quality, work force) the equipment hours required are the same regardless of the work schedule. If the schedule is reduced while maintaining the same production, the savings in supervisory, overhead, and shift differential costs cannot justify the capital cost of more equipment of equal size and quality.

Table 4. Typical Taconite Costs Shown as a Percentage of Total Cost Excluding Stripping, Royalties, Depreciation, and Taxes

Cost Item	Cost		Cost Range*			
	Labor, %	Supplies, %	Labor		Supplies	
			Low, %	High, %	Low, %	High, %
Mine operating						
Drill and blast		2.7				
Load and haul		2.2				
Other		1.4				
Subtotal	2.6	6.3	2.0	3.6	4.5	8.0
Mine maintenance						
Drills		0.3				
Shovels and trucks		1.8				
Other		1.4				
Subtotal	2.7	3.5	2.2	3.4	2.0	5.6
Crushing	2.0	3.9	0.4	4.2	0.8	5.9
Concentrating	5.1	27.2	4.7	6.0	13.0	42.9
Pelletizing	5.5	25.6	4.5	9.1	18.8	37.4
Employee Benefits	8.5	—	3.4	10.2	—	—
Overhead and Administration	4.4	2.7	2.9	5.5	1.5	6.8
Total	30.8	69.2	24.9	35.6	64.4	74.6

* Cost variations due to size of operation, weight recovery, equipment, and crushing-concentrating pelletizing flowsheet.

A change in equipment size, for example, can produce economic benefits. An operation changing from 100- to 170-ton trucks would improve costs as shown in Table 6.

In addition to the direct costs, there is a savings in benefits, overheads, supervisory labor, and clerical labor:

Benefits and overheads	\$ 9,500/year × 76 employees	\$ 722,000
Supervisory labor	\$48,000/year × 7 employees	336,000
Clerical labor	\$38,000/year × 3 employees	114,000
Subtotal: indirect costs		\$1,172,000
direct costs		3,849,000
Approximate total annual savings		\$5,021,000

The replacement of 100-ton trucks with 170s would therefore return the initial investment in about 4.3 years (based on typical 1982 Mesabi Range costs).

NATURAL ORE MINES

The advent of pelletizing in the 1950s created such a great improvement in blast furnace efficiencies that other iron ores were almost completely phased out of the steel-making process by the later 1970s. Although pellets are now the primary source of iron, a trend back to natural ores is

Table 5. Lease vs. Purchase

Cost	Five-Year Lease			Ten-Year Lease

Total cost, present valued @ 10%	—	1,014,200	600,400	1,169,500	973,300

¹ Lease costs based on a rate of 5.5% of principal payable quarterly in arrears with "balloon" payment for ownership equal to 68% of original value (10% tax credit taken in first year).

² Lease costs based on a rate of 4.0% of principal payable quarterly in arrears, with guaranteed residual value equal to 68% of original cost (10% tax credit kept by lessor). If lessor must sell equipment for less than \$612,000, lessee must pay the difference. Example: assume equipment is sold for 30% of original value (\$270,000), then lessee must pay \$342,200, increasing total lease cost to \$1,062,000, or a present value of \$758,200.

³ Lease costs same as note 1 except no "balloon" payment. Purchase equipment at lease termination for fair market value, i.e., estimate 10% of original cost.

⁴ Lease costs same as note 2 except no guaranteed residual value. Lessor sells to others at fair market value.

becoming evident primarily due to the huge reserves of high grade ore in Brazil and Australia.

Natural ore mines have the advantage of lower or no concentrating costs and the disadvantage that sintering or pelletizing is required to produce a high quality blast furnace feed.

Mine operating costs in North America are approximately one-half that of taconite operations and vary from \$9.00 to \$13.00 per long ton excluding the stripping cost. Operating costs in South America are approximately one-half that in North America primarily due to:

Continuous operations. North American mines are normally closed during winter months because of freezing.

Lower labor costs.

Table 7 illustrates the typical cost percentages for natural ore mines on the two continents.

SUMMARY

Basic philosophy, responsibilities, cost control methods, and equipment selection procedures are not significantly changed by time or location. The application of this material to a particular operation, however, must be updated to current inflation, interest rates, governmental regulations and taxes, and to prevailing labor, material, and equipment costs.

ACKNOWLEDGMENT

The assistance of Frank B. O'Connor in preparing the Leasing vs. Purchasing portion is appreciated.

7.2.2. Mining Coal in West Virginia with a 72-Cubic Yard Dragline

KENNETH WOODRING
RUTH SULLIVAN

INTRODUCTION

Ashland Coal, Inc. founded in 1975, is based in Huntington, WV. The company markets nearly 4.5 Mt (5 million st) of coal annually to both domestic and foreign customers. Operational areas include eastern Kentucky and southern West Virginia. Total coal reserves are approximately 904 Mt (1 billion st). Hobet Mining, Inc., Ashland's West Virginia operating division, is headquartered at its No. 21 mine site in Boone County near Danville. Ashland's West Virginia holdings include about 182 kha (45,000 acres) representing reserves totaling 361 Mt (400 million st) of high quality steam coal. Mining is presently conducted in Boone and Logan Counties.

Ashland Coal acquired Hobet Mining in March 1977. At that time a preparation plant (Beth Station) with a capacity of 1.8 Mt (2 million st) was under construction on the Hobet 21 mine site. One of the first orders of business was to design a mine plan to provide 1.8 Mt/a (2 million stpy) of production for the preparation plant which has a 20-year life. The coal production would come from a more than adequate reserve base. The decision was made to develop the surface reserves first and maximize cash flow by potentially more economical surface mining methods.

Through the early 70s surface mining in mountainous southern West Virginia was generally done by contour mining and/or augering techniques. As market conditions changed and larger equipment became available, in the mid-70s, contouring at several mining locations gave way to mountaintop removal in order to maximize reserve recovery. The mountaintop method was explored for the development of the Hobet 21 mine property. This mining method involves the removal of all overburden and coal from the top of the mountain down to the lowest coal horizon to be mined in a particular mountain. Generally, the overburden is hauled to valley fills in hollows adjacent to the area being mined. Overburden can also be backstacked on the solid mountain area where the lowest seam has been removed. These particular coal seams are relatively flat lying. The overburden consists mostly of shale or sandstone and must be drilled and shot.

Generally, loaders and trucks or shovels and trucks have been used for this type mining. The contiguous acreages at Hobet's 21 mine site prompted the consideration of larger mining equipment, i.e., a dragline.

HOBET MINING METHODS

A look at a typical cross section of the reserve is now appropriate. Fig. 1 shows the various available coal seams, the relative thicknesses of overburden separating them, and the original ground line. Average relief is 152 to 183 m (500 to 600 ft). Typical mountaintop removal involves removal of all overburden down to the middle Stockton seam and placement of the overburden in the adjacent valley with some backstack in the middle Stockton bench. Certainly, the dragline application on the original topography would be impossible because of the steep slopes, irregular shapes, and overall relief. A dragline requires a relatively flat surface area on which to operate.

Using some imagination, look again at the cross section and consider removing the overburden only to the 5-Block level, placing it in the adjacent valley fill on the right. The result is shown in Fig. 2. The flat area on which to work the dragline is now available. Placing a dragline on the 5-Block level and digging to the upper Stockton creates a rather conventional dragline operation. The adjacent valley fill then provides an area to cast the pit.

Looking at Fig. 3, notice the dragline has mined the first pit, placing the spoil on the adjacent fill area. Fig. 4 shows that some of the subsequent pits have been mined, and the dragline is about half complete with the mining area. Finally, Fig. 5 shows the regraded section after the mining is complete. Notice how the spoil piles have been leveled and the outslopes are graded and benched. The resulting topography is more gentle than the original, but the general trend of high and low areas has not changed.

Fig. 6 illustrates the plan view of a potential mining area. The seam outcrops are marked. Fig. 7 indicates the appearance of the same area after the overburden is removed down to the 5-Block seam and placed in the adjacent fills. Again, the 5-Block bench becomes the flat working area for the dragline. Notice the map shows additional mining was done in three areas. These additional cuts are to the Stockton level. They create casting areas for the dragline in the absence of valley fills. In fact these are relief cuts made for the dragline with the loader/truck mining method. All the overburden from above the 5-Block seam and the relief cuts was incorporated into valley fills and dragline access ramp. Fig. 8 demonstrates how the actual dragline pits are laid out. Pits are numbered consecutively; the arrows associated with the pit numbers indicate the direction of the dragline movement and casting.

EQUIPMENT SELECTION

We have talked only generally about equipment assignments. Let's take a closer look. Loader/truck or shovel/truck is appropriate for overburden from the top of the mountain down to the 5-Block. A loading shovel is most appropriate on the interval between the Middle Kittanning and 5-Block seams due to the larger bench widths and greater volume of overburden. The smaller irregular area above the Middle Kittanning is more appropriate for the loader/truck combination. The parting between the Upper and Middle Stockton seams is quite thin [approximately 2.4 m (8 ft)] and is another good loader/truck candidate. A shovel would not be desirable for use on the 2.4-m (8-ft) digging face and lacks the mobility to move quickly between pits. The dragline is best suited for the interval between the 5-Block and Upper Stockton seam.

Some assumptions were necessary for designing a mine plan as to the relative costs of overburden removal by different types of equipment. These assumptions were, of course, elaborated on with respect to the economic evaluation of the overall project. However, this is not a part of this discussion. Ashland's management and engineers assumed that the dragline would operate at 50%, or half the cost of loader/truck and the shovel/truck would operate at 75% the cost of the

Fig. 1. Original section.

Fig. 6. Virgin mining area.

loader/truck procedure. Loader/truck method was used as the basis for comparison because most of Ashland's existing cost data was generated using that type of equipment. Using these criteria the decision was made to maximize the amount of overburden to be removed by the dragline and to utilize the shovel/truck process on the greatest portion of remaining overburden.

Approximately 4047 ha (10,000 acres) of coal-bearing land was required for the 20-year mine life, and that roughly

measures about 8×4.8 km (5×3 miles). The area was divided into mining areas by topographical characteristics. Fig. 8, in fact, represents the first mining area that was examined and it is typical of all the areas. The general rule of design is to maximize pit lengths and strategically locate valley fills to accept spoil from initial cuts. This minimizes the number of relief cuts, leaving more overburden for the dragline. Notice that where pit lengths are short the machine is alternated between pits to allow adequate time for coal

Table 2. General Equipment Requirement

Production requirement (clean tons)	2,000,000
Average plant recovery	79%
Raw tons required (2,000,000 ÷ 0.79)	2,531,600
Overburden ratio	10.01:1
Total overburden removal requirement	25,341,300
Maximum dragline percentage	53%
Maximum dragline overburden portion	13,430,900
Conventional percentage	47%
Conventional overburden portion	11,910,400

Metric equivalent: ton × 0.904 184 7 = t.

and parting removal. The ramp shown is set on a 6% grade and provides dragline access to the 5-Block elevation. Later it serves as the exit ramp when mining is completed. Grade changes such as these are necessary only three times in the mine life. After the third area is mined, the machine stays at the 5-Block level. The dragline has a 1.6-km (1-mile) walk between the first and second mining areas—the walk will require approximately 24 hr. All other mining areas contact each other.

After the mine layout was completed, each area's overburden was categorized into dragline work and conventional shovel/truck or loader/truck work. Layouts include cut and fill balances for conventional mining and pit layouts for the dragline. The results of this examination appears in Table 1.

An overall mining ratio of 10.01:1 is shown. The table also points out that 53% of the total overburden could be moved with a dragline. All parting between the Upper and Middle Stockton seams is included with the conventional equipment work.

For annual mine production of 1.8 Mt (2 million clean st) at 79% recovery through the preparation plant, the numbers in Table 2 apply. The dragline application could effect up to 10.3 Mm³ (13,430,900 bank cu yd) annually of the 19.4 Mm³ (25,341,300 bank cu yd) total requirement.

Dragline Sizing

Since the annual production requirement has been determined, we can now look at dragline sizing, actually, a range of sizes. To start, each manufacturer of walking draglines offers an appropriate model to accommodate Hobet's requirements. Each model is available with various bucket-boom configurations to suit different mining conditions. Therefore, once a model was selected, we were still working with a range of bucket-boom options. The options were:

Bucket Size, m ³ (BCY)	Operating Radius, m ³ (ft)
49.7 (65)	94.2 (309)
55 (72)	90.2 (296)
58.1 (76)	82 (269)

Annual production capabilities will be discussed first and then boom geometry. Table 3 illustrates annual operating hour calculations for a dragline operation. Table 4 summarizes dragline cycle calculations and calculates productive capability per operating hour per bucket yard. The appropriate annual production for the aforementioned options is shown in Table 5. By this analysis the 58.1-m³ (76-yd) option would seem most productive, but let us now consider boom geometry.

Boom geometry is a function of pit geometry. Pit geometry is, of course, a function of pit width and overburden

depth. The pit was assigned a 36.6-m (120-ft) width to provide adequate width for coal and parting removal. Overburden depths (distance from 5-Block to Upper Stockton) vary over the mining areas and are represented in Fig. 9. While the average depth is 28 m (92 ft), the dragline will dig as deep as 35 m (115 ft) and as shallow as 23 m (74 ft). These extremes must be taken into consideration as well as the average depths.

Another factor affecting boom geometry is the blasting technique. Two techniques that could be applied are open-face and buffered. Open-face blasting would involve shooting only the width of the pit the dragline was digging. It would provide a solid highwall to dig against and provide for some cast yardage from the blasting operation. Problems associated with the method include the loss of bench height during shooting and difficulties in sequencing blasting with the dragline movement and coal parting removal.

Buffered shooting would be completed many pits ahead of the dragline, therefore eliminating, to a great extent, the sequencing associated with open face blasting. This method maintains bench height and, from experience at the mine site, provides better fragmentation of material. In consideration of these factors it was decided to design the operation for buffered shooting. The highwall angles Hobet used are 1/4:1, the swell factor is 35%, and the spoil angles are 38°. The machine center pin is held 12 m (40 ft) from edge of the bench.

The three machine options, Fig. 10, are demonstrated on a pit cross section with the average digging depth of 28 m (92 ft). The maximum reach capability of each option is the working radius less the 12-m (40-ft) setback for the center

Table 4. Dragline Cycle Calculations

Drag time	15 sec
Loaded swing	20 sec
Dump time	3 sec
Empty swing	18 sec
Preparation to drag	3 sec
	59 sec
Swell factor	0.74
Bucket fill	90%
Operator efficiency	90%

$$\text{Yd/hr/bucket-yd} = 60 \text{ sec/min} \times \frac{60 \text{ min/hr}}{59 \text{ sec/cycle}} \times 0.74 \times 0.90 \times 0.90 = 36.57$$

Metric equivalents: yd × 0.9144 = m; cu yd × 0.764 554 9 = m³.

Table 5. Dragline Production Capabilities

Working Radius	Bucket Size	Operating hr/yr	Yd/hr bucket-yd	BCY/Yr
269	76	4803	36.57	13,349,100
296	72	4803	36.57	12,646,500
309	65	4803	36.57	11,417,000

Metric equivalents: yd \times 0.9144 = m; cu yd \times 0.764 554 9 = m³.

pin. The 49.7- and 55-m³ (65- and 72-cu yd) options reach the spoil peak easily digging 28 m (92 ft), but 58.1 m³ (76 cu yd) falls short and requires a bench extension. Any bench extension for this mining cross section requires a significant percentage of rehandle for the first increment as is demonstrated by the cross-hatched area. The total bench extension required here was 0.6 m (2 ft). The first increment required 25% rehandle, the remaining 0.6 m (2 ft) required an additional 2% rehandle. The total 27% rehandle is counter-productive and undesirable, thus making the 58.1-m³ (76-cu yd) option less productive than the 58-m (72-cu yd) unit.

Moving up toward the maximum 35-m (115-ft) vertical digging height the 58-m³ (72-yd) machine reaches its limitations at 31.5 m (103.5 ft). To go higher we would have to do a costly bench extension as described or do what is pictured in Fig. 11. Here the spoil line intersects the top of the Upper Stockton seam rather than the bottom of the Middle Stockton as shown in Fig. 10. The shifting of the spoil allows the 58-m³ (72-yd) machine to dig up to 35 m (115 ft). The 58.1-m³ (76-yd) still requires a bench extension, the 49.7-m³

(65-yd) is, of course, adequate. This spoil shifting creates some rehandle in the coal pit by loaders, but the amount is relatively small. Also, referring back to Fig. 9, only three of the mining areas would require a spoil shift for the 58-m³ (72-yd) machine, so the other 17 can be mined without any rehandle.

As a result of studies like these and consideration of the flexibility and conservatism, it was determined the best-suited machine option is the 58-m³ (72-cu yd) bucket with the 90.2-m (296-ft) working radius. The unit has an annual operating capability of 9.67 Mm³ (12,646,500 bank cu yd). Although this is less than the 10.3 Mm³ (13,430,900 bank cu yd) possible as shown in Table 2, the move up to the next larger model machine is great, in both size and cost. The result would be a machine far too large for the application.

Shovel/truck Portion

Considering the 19.4 Mm³ (25,341,300-bank cu yd) total requirement for the mine, the conventional portion becomes 9.71 Mm³ (12,694,800) as a result of the foregoing exercise.

Fig. 9. Average overburden height for dragline areas. Metric equivalent: ft \times 0.3048 = m.

SURFACE MINING

Fig. 10. Ranging diagram, average overburden.

As discussed before, the shovel/truck portion of this amount should be maximized to the fullest extent. The physical limitations are basically the amount of overburden between the 5-Block and Middle Kittanning seams and the amount of overburden in relief cuts on the Stockton which are large enough to work a shovel. This number for the 20-year mine life is 107 Mm³ (140 million bank cu yd) or 5.4 Mm³ (7 million bank cu yd) per year. A 20.6-m³ (27-cu yd) loading shovel meets this requirement on a five-day three-shift sched-

ule as indicated in Table 6. The machine is matched with 120-ton haulers.

Loaders

The remaining conventional yardage is left for 9.6-m³ (12½-cu yd) loaders teamed with 85-ton (108.5-t) trucks. These units provide the mobility and flexibility to make the small relief cuts, pull partings, and perform general support work for the larger equipment. Four such units are necessary

on a five-day two-shift schedule to complete the overburden removal requirement. Annual production per loader unit is demonstrated in Table 7.

Table 8 summarizes the overburden removal equipment. The total capability of the selected equipment meets the annual mine requirement.

EQUIPMENT PHASE-IN

Dragline

The dragline, a Bucyrus-Erie 1570W, was purchased in February 1981. Erection was started in November 1981 and completed in March 1983. The machine walked off the erection pad March 26 and started digging on the 28th. The machine sits on a 20-m (66-ft) diam base, the walking shoes are 3.7 \times 21.3 m (12 \times 70 ft) each. The working weight of more than 3.6 Mg (8 million lb) includes 453.6 kg (1 million lb) of ballast. The boom is 99 m (325 ft) long on 35°. Hoist and drag ropes are 95.25-mm (3½-in.) diam. Motor generator sets total 7.46 MW (10,000 hp). Twenty-two thousand nine hundred volts ac enters the machine and is reduced to 6900 volts ac in a 10-MVA transformer.

The dc motors are as follows:

Drag	2.98 \times 969.8 kW (4 \times 1300 hp)
Hoist	4.48 \times 969.8 kW (6 \times 1300 hp)
Swing	2.98 \times 77.96 kW (4 \times 1045 hp)
Propel	0.746 \times 373 kW (1 \times 500 hp) [per side]

Table 8. Overburden Removal Equipment List

No.	Item	Size, yd	Annual BCY
1	B-E 1570W dragline	72	12,647,000
1	B-E 295 BII shovel	27	6,908,000
4	Cat 992C	12½	6,328,000
Total			25,883,000

Metric equivalents: yd \times 0.9144 = m; cu yd \times 0.764 554 9 = m³.

Hobert's machine has six hoist motors rather than the standard four and 77.96 kW (1045 hp) swing motors rather than the standard 596.8 kW (800 hp). This optional equipment was added to ensure optimum cycle times in all situations. More specifically, the amount of swing limiting and/or hoist limiting has been favorably reduced.

For the purpose of erection a 39.6-m (130-ft) long by 30.48-m (100-ft) wide by 12.2-m (40-ft) high steel building of rigid frame construction was built on wheels and rails over the site. The enclosure covered the base and revolving frame during welding, machining, and equipment alignment. The wheels and rails allowed the building to be moved away from time to time, permitting the 122-t (135-st) erection derrick to set the necessary parts in place. On completion of the revolving frame the building was moved away for the last time. The same structure now serves as a permanent four-bay shop building approximately 122 m (400 ft) from the erection pad. A 929-m² (10,000-sq ft) office and warehouse was attached to complete the mine's new service complex.

An on-board computer was added to the dragline to monitor productivity and to track any delays, providing a high degree of accuracy. The associated computer console, in the operator's cab, visually aids the operator with machine positioning and monitoring cycle times. As different digging techniques are explored, the system will provide rapid documentation for comparison purposes. Component life can also be studied with the system.

Loading Shovel

The 20.6-m³ (27-cu yd) loading shovel is a Bucyrus-Erie 295-BII. Purchased in December 1981, the machine was placed in operation in July 1982 following a two-month erection period. Machine electricians are Bucyrus's new static a-c "Acutrol" system—it is the first such machine operating in the United States with General Electric components. The a-c motors are as follows:

Hoist	0.746 \times 932.5 kW (1 \times 1250 hp)
Swing	1.49 \times 167.9 kW (2 \times 225 hp)
Crowd	0.746 \times 167.9 kW (1 \times 225 hp)
Propel	0.746 \times 503.6 kW (1 \times 675 hp)

The trailing cable voltage is 7200 ac. The working weight is slightly less than a 680 kg (1½ million lb). The boom is 15.8 m (52 ft) high. Shovel benches are held to a vertical height of 13.7 m (45 ft).

Haul Trucks

Matched with the 295-BII shovel are WABCO 120D haul trucks. The trucks provide a three-pass loading match—the double back-in loading system is employed. The trucks were purchased with the 776 deep pit wheel option and extended range dynamic braking to aid in safely handling the downhill hauls from the 5-Block level to the fills.

Bulldozers	14

Metric equivalents: yd \times 0.9144 = m; in. \times 25.4 = mm, ton \times 0.904 184 7 = t, gal \times 0.003 785 4 = m³.

Loaders

Wheel loaders for overburden removal are Cat 992C models. Equipped with 9.6-m³ (12 $\frac{1}{2}$ -yd) buckets, the units four-pass load 85-ton (76.9-t) Cat 777 end-dump trucks.

Dozers

The mine's dozer fleet is composed of Cat D10s, D9s, and D8s. Spoil leveling is generally done with the D10s. The D9s are normally used to feed material to end loaders and the D8s are used on fills and drill benches.

Drilling

Drilling varies in size, dependent upon the application. Dragline drilling is done with a Marion M-3 unit equipped with a 269.9-mm (10 $\frac{5}{8}$ -in.) rotary bit and 18.3-m (60-ft) drill pipe. Since maximum dragline overburden is 35 m (115 ft),

Annual BCY	12,646,000	15,711,000

Metric equivalent: cu yd \times 0.764 554 9 = m³.

the M-3 can drill all situations with only one steel change. The unit is equipped with Marion's automatic drill control system and operates on 7200 ac. Drill patterns are normally 8 \times 8 m (27 \times 27 ft).

A Robbins RR10 drill is used with the shovel. Equipped with a 22.9-cm (9-in.) rotary bit and 7.6-m (25-ft) drill pipe, the machine drills on a 5.5 \times 5.5 m (18 \times 18-ft) pattern. Driltech D40s and D50s round out the drill fleet and provide drilling for the loader units.

Loading

Coal loading is accomplished with both 998B and 992C Cat loaders. Coal shooting is unnecessary; the loaders break the coal from the seam quite easily because of the well established cleavage patterns. Haulage is in 65-ton (58.8-t) Cline and 85-ton (76.9-t) Dart haulers. Tandems have been used rather than bottom-dump trailers due to the mile-long grade at a 9% drop to the preparation plant.

Major equipment is listed in Table 9.

MANPOWER

Manning levels for the operation are summarized in Table 10. Production for the 200 UMWA surface mine employees will be approximately 36 t (40 tons) per man-day.

OPERATING EXPERIENCE

Since the first writing of this article about the time of the dragline startup in April 1983, Hobet has gained much information on the operation and performance of this machine. The original approach was very conservative due to the difficult application. Our experience since April 1983 has demonstrated the machine to be more productive and flexible than anticipated.

The operating statistics documented by the dragline's on-board computer readily indicate this and have been incorporated into the current budgeted operating performance, Table 11. The production rate of 12 Mm³ (15,711,000 BCY per year) reflects a higher BCY operating hour rate of 3250, mainly attributable to the higher operator efficiency and bucket fill factor.

Table 12. Shovel Operating Statistics

Table 13. Loading Statistics

Equipment	Size, yd	Orig. Budget, Annual BCY	Current Budget, Annual BCY
BE 1570W dragline	72	12,647,000	15,711,000
BE 295 BII shovel	27	6,908,000	6,517,000
992C (three shifts)	12½	—	2,342,000
992C (two shifts)	12½	(× 4) 6,328,000	1,562,000
Total		25,883,000	26,132,000

Metric equivalents: yd × 9144 = m, cu yd × 0.764 544 9 = m³.

The current budgeted operating statistics are intended to reflect the average performance for the life of the machine. The dragline's actual production statistics for fiscal 1984 indicate a better performance because the machine is still relatively new.

The increased production and flexibility of the dragline has permitted Hobet to revise the pit layout in some areas and cycle the dragline through a series of shorter pits in three or sometimes four adjacent areas. This more complex pit sequencing and design, while incurring more bench extension, rehandle, and walking, has two advantages: it provides additional time for coal removal from the pits and maximizes the percentage of overburden designated to the dragline.

The increased production, and maximization of the percentage dragline overburden, coupled with a maximum capacity at the preparation plant of 1.8 Mt/a (2 million stpy) permitted the mine to reach budgeted coal production while maintaining the previously established end loader output. It is envisioned, however, that the number of spreads will eventually increase as the ratios for the development work above the 5-Block seam increase in the future mining areas.

The shovel has not performed as expected due to higher than expected operational delays created by a shortage of trucks; however, with the recent addition of a fifth Wabco 120, the shovel performance is expected to match budget expectations, Table 12.

The endloaders have performed as expected. One spread operates three shifts per day primarily in inter burden between the Upper and Middle Stockton while the other operates two shifts a day on development work along with the shovel. The total yards handled per year is 20 Mm³ (26,132,000 bank cu yd), Table 13.

The approximate capital cost expenditures for major equipment is shown in Table 14.

7.2.3 Cost of Mining Eastern Coal*

How much does it cost to mine a ton of coal? This is the most complicated and critical question in the coal industry. It is crucial to know not only how much it costs to mine, but also what price the market will bear. A piece of coal with its own inherent overhead must be matched to the marketplace. This basic fact governs how, when, and if the coal will be mined.

There are some constants in mining expenses, but there are endless variables. To arrive at a reasonably accurate figure for mining a ton of coal, it is necessary to set forth certain conditions. In the following example the coal tract is 50.6 ha (125 acres) in West Virginia to be mined by the contour surface method. The seam is 101.6 cm (40 in.) thick. Hiring, equipment selection and procurement, and permit application may all be done simultaneously, but the permit must be secured before any mining or construction can take place.

PERMITTING AND BONDING COSTS

Permitting

When the permit application goes to the West Virginia Dept. of Natural Resources (DNR), it must be accompanied by a \$500 filing fee. This is *not refundable* in the event the permit is denied. The NPDES permit, also under the jurisdiction of DNR, requires an additional fee of \$50. Then there is the lands inquiry fee of \$100 to determine if the proposed site contains any unique historical, environmental, or geological qualities. When a surface mine application (SMA) number is assigned, the prospective operator must purchase legal advertising to announce his intention to mine coal, to alert any potential opponents to the permit. This ad must run on four separate days, each a week apart, and, in this case, will cost a total of about \$150. The legal ad process will be repeated three times, one for each phase of the bond release. Add in the cost of legal ads for intent to blast and the total advertising bill is \$750, making the total face cost of the permit application of \$1400.

Bonding

The bond is the amount of money committed by the operator to insure proper and complete reclamation. If reclamation standards are not met, the bond is forfeited and presumably used to contract reclamation for the area.

The bond is set by law at \$1000 per acre (\$10,000) minimum. For a permit of 101.6 ha (125 acres), the bond will be \$125,000. It would be extremely difficult for a new business to qualify for bonding by insurance or related companies. Because a mining bond is more in the nature of collateral, as opposed to an actual cash outlay, the qualified operator can obtain bonding at a rate which averages about \$12.50 per \$1000.

Following successful reclamation, the bond is released in three phases. Phase 1 comes at the end of the mining operation when the entire area has been regraded to specifications. This amounts to about 60% of the original bond. Phase 2, an additional 25%, may be released two years after completion of reclamation when vegetative cover is well established. Phase 3, the final 15%, is held for an additional three years, a total of five years after completion of the

operation. In the case cited here this takes place eight years after the job was begun.

The cost on Phase 1 of the surety bond, \$125,000 for three years, would be \$4687.50. Phase 2, \$50,000 for two more years, will cost \$1250. Phase 3, \$18,750 for three years, amounts to \$703.12. Thus, the total bonding cost would be \$6640.62.

ENGINEERING AND CONSTRUCTION

The permit application is quite voluminous and requires engineering expertise which is usually beyond the in-house capability of the small company. For an operation of the size under discussion, plans for haul roads, drainage and valley fills, surveying, maps, and hydrological studies will commonly cost about \$25,000. Again, this is a front-end cost which is not recoverable in the event of permit denial.

The construction phase of the operation will entail two major projects. One is the drainage system, of which the primary component will be sediment ponds. Three ponds of average size, professionally designed to capture all runoff from a mining operation, will cost about \$35,000. The haul road, like all other mine construction, must be carefully engineered. The typical haul road in West Virginia will cost about \$100 per foot. Thus, a road of only one mile in length will run about \$528,000. The total engineering and construction costs will be \$588,000. These are all expenses which are incurred *before* any coal production is carried out.

EMPLOYMENT COSTS

A permit of 101.6 ha (125 acres) can be expected to yield about 30 ha (75 acres) of minable coal. At 2200 t/ha (6000 net st per acre), the projected total tonnage from the permit would be 408 kt (450,000 st) net.

Setting a production goal of 13.6 kt (15,000 st) per month and allowing for start-up, slow production as the permit plays out, and final reclamation, the projected life of the operation would be about 36 months. Given current productivity figures, this calls for a work force of about 20 miners, plus at least one foreman.

Wages

The average coal miner in West Virginia costs \$585.69 per week (1983 figures). This amounts to a weekly payroll, including the foreman, of \$12,463.80. Times 52, the annual payroll is \$648,117.60. For the three-year life of the operation, and naively allowing for no wage increase over that period, the basic employment cost would be \$1,944,352.80. This, as all employers know, is the tip of the iceberg.

Surcharges

Coal employers, even surface coal operators, pay 50¢ per ton into the federal black lung fund. This amounts to an additional \$225,000 over three years. The state collects, for the same purpose, 2.4% of the payroll and collects it three years beyond the life of the operation. In this case, the cost would be \$93,328.93.

Workers' compensation is paid to the state at varying rates. The rate for new companies (less than five years in business) in the coal industry is \$6.50 per \$100 of payroll. This would amount to \$126,382.93 over three years.

Both the state and federal governments take a bite for unemployment compensation. The state gets an annual amount equivalent to 5.5% of the first \$8000 per employee.

*Adapted from an article by Dan Miller in *Green Lands*. Costs cited are those of 1983.

This would be \$9240 per year, \$27,720 for three years. The federal government gets 0.2% of the first \$7000 per employee per year, or \$294 per year, \$882 for three years.

FICA, the federal social security tax, is 7% of each employee's salary. There is a ceiling on this, but it is raised each year. For the 21 employees, the cost will be \$45,368.23 yearly and times three is \$136,104.69 for the life of the operation.

The cost of government is summarized in Table 1.

Other Fringe Benefits

There are other fringe benefits as well. Standard hospitalization, for instance, will cost about \$375 per month per employee. In this case, the expense will be \$7875 per month, \$94,500 per year, \$283,500 for three years. Practicality dictates that each employee undergo a thorough examination prior to employment to identify preexisting medical conditions. This would amount to an expense of about \$4500.

The UMWA extracts \$1.60 per ton from signatory companies for its pension fund. That is \$720,000 on this permit. The Union also gets \$1.07 per hr. Over three years that is 113,100 hr, or a total of \$115,022.70. Costs of unionism are summarized in Table 2.

The Mine Safety and Health Administration (MSHA) also requires a bathhouse for employees or payment of a "bathhouse waiver." Small companies, particularly operating in a given area for only three years, will find it more convenient and economical to pay the waiver of \$2 per day per employee. That adds another \$31,200 to the employment costs.

There is also the uniform allowance. This amounts to \$150 per year per employee, payable on the first payday for each employee. Even assuming no turnover in the work force, this cost would be \$9000 for three years.

Training is required for all employees in surface mining procedures. Annual refresher training for this work force will cost \$10,002. Training for the required emergency medical technician (EMT) will cost \$1266.92.

Additionally, a labor bond must be posted with the Labor Commissioner of West Virginia to ensure payments of wages and benefits in the event of shutdown. The bond amounts to four weeks of payroll plus 15%. At current rates, the cost of the bond will be \$6206.97.

Total Payroll

Thus, payroll nearly doubles, considering all the auxiliary costs of putting a miner to work. To be precise, the payroll is \$1,944,352.80 and the extra costs amount to \$1,790,117.14, for a total cost of employment of \$3,734,469.94.

Pension fund (by hour)	0.25
Uniform allowance	0.02
	\$1.87

EQUIPMENT

The variety of equipment "spreads" and methods of obtaining, financing, and disposing of them is endless. The average surface mining operation will involve bulldozers, loaders, off-highway trucks, drills, graders, and other trucks specialized for such functions as coal hauling, explosives storage and hauling, water pumping, water spreading, maintenance, seeding, welding, emergency transport, and others. Site, market, and company considerations dictate the particular combination of these pieces to be used on any particular operation. There is no "average."

However, using accepted industry figures for cost-per-ton of standard surface mining functions, and deleting from these employment costs covered previously, approximate estimates can be made on the cost of operating and maintaining the necessary equipment over the three-year life of the project.

In surface mining, by far the single biggest expense is that of exposing the coal, that is, removing and storing, or disposing of, overburden. In mining with a 10:1 overburden ratio, a good-to-average situation in West Virginia, this expense will amount to \$7,593,750 over the life of the operation. Loading the coal for transport to the tippie will be \$393,740. Haul road maintenance will be \$196,875. Final regrading of the slopes and preparing for seeding will cost \$393,750. These four basic functions will total \$8,578,125, which represents equipment costs on this project.

OTHER OPERATING EXPENSES

Assuming the company does not own its own tippie, it will encounter a cost of \$2 per raw ton for this function. The operator can expect a loss of at least 20% of raw tonnage during the cleaning process. To net 408 kt (450,000 tons) of clean coal, it will be necessary to haul and clean 526 kt (572,500 raw tons). Therefore the tippie cost will be \$1,125,000.

The standard cost for hauling is \$1 per ton for the first mile and 10¢ per ton for each additional mile. Assuming a 9.7-km (6-mile) haul, the cost would be \$1.50 per raw ton, or \$843,750.

Another common operating cost is "wheelage," that is, hauling coal over the property of an adjacent landowner. The standard fee is 10¢ per ton, a total of \$56,250.

The actual revegetation of reclaimed land is another function likely to be contracted by the small mining company. At approximately \$700 per acre, this will cost \$93,750.

In many cases, the coal operator is mining on private property and therefore must pay a royalty to the mineral owner. This party gets either a price per ton rate or, more likely, a negotiated percentage of the sale price, typically 8%. Assuming a sale price of \$38.50 per ton, the royalty will be \$1,386,000.

TAXES AND FEES

Government, in addition to playing a leading role in employment costs, has several direct taxes for the coal op-

Table 3. Tons Mined Required to Meet Overhead Costs

Overhead Item	Cost	Tons
Permits	\$ 1,400.00	36
Bonding	6,640.62	173
Engineering	25,000.00	649
Construction	588,000.00	15,273
Payroll	1,944,352.00	50,503
Government imposed payroll expenses	626,894.44	16,283
Union imposed payroll expenses	875,222.70	22,733
Hospitalization and medical	288,000.00	7,481
Overburden removal	7,593,750.00	197,241
Coal loading	393,750.00	10,227
Haul road maintenance	196,975.00	5,114

Hauling	843,750.00	21,915
Wheelage	56,250.00	1,461
Revegetation	93,750.00	2,435
Royalties	1,386,000.00	36,000
Property tax	550.80	14
Fuel tax	56,250.00	1,461
B&O tax	667,012.50	17,325
Abandoned Mine Lands Fund	157,500.00	4,091
Special Reclamation Fund	4,500.00	117

erator. Basic to these is the West Virginia Business & Occupation (B&O) tax, which squeezes coal at the rate of 3.85% of the sale price. On 408 t (450,000 tons) net at \$38.50 per ton, the B&O tax comes to \$667,012.50.

The coal property tax in the county where the permit is located is currently (1983) \$255 per acre. For 30 ha (75 acres) of coal, the tax base would be \$19,125, which is assessed at a rate of 60%, or \$11,475. The Class III Levy is 2.4%, or \$275.40, which would be the actual assessment for the first year. Assuming the coal is mined at the rate of one-third during each of the three years of operation, the actual assessment in the second year would be \$183.60. The taxes for the third year will be \$91.80, for a three-year total of \$550.80.

Fuel tax is extracted at the rate of 4.85¢ per gal. It takes a little over 2 gal of fuel to mine a ton of raw coal. This means a tax of approximately 10¢ per ton, or \$56,250 over three years.

The federal Office of Surface Mining takes 35¢ per net ton for the reclamation of abandoned mine lands. This amounts to \$157,500 on this operation. West Virginia currently gets an additional 1¢ per ton for its own Special Reclamation Fund, a total of \$4500.

The total direct taxes and fees on this operation will amount to \$885,813.25 over three years, or \$1.97 a ton. If that does not seem like much, consider that such government revenue is generated from one small operation. Multiplied by West Virginia's total 1983 tonnage, these figures amount to one quarter of a billion dollars for that year. These are only direct taxes and fees and do not include the various government-imposed payroll expenses.

VARIANCES

The hypothetical situation set forth here required numerous assumptions. It should be emphasized that this would be a relatively small operation. Even so, it is clear that any adjustments in costs ricochet through three years and 408 kt (450,000 tons) with a startling effect.

For example, this operation was calculated to need 20 employees plus one foreman. The addition of even one hourly worker adds \$129,384.85 to the overhead in three years. A wage increase of only 50¢ per hour adds \$67,045.83 to total employment costs.

A decade ago the West Virginia State Legislature tacked on a modest 0.35% surcharge to the B&O tax (for coal *only*). This increases the hypothetical mining costs here by \$60,637.50. Suppose the financially troubled social security system is "transfused" with an additional 1% in FICA payments. That is another \$19,443.53 in overhead.

Wheelage, the rate paid for hauling coal across someone else's property is generally 10¢ a ton or, if the route crosses the grounds of two property owners, there is an additional 10¢ per ton, another \$56,250. Add five miles to the "haul," the distance from mine to tipple, you have increased the cost by 50¢ a ton, or \$225,000 added to overhead.

Table 4. Overhead Cost per Net Ton

Permit and bonding	\$ 0.02
Engineering	0.06
Construction	1.31
Basic payroll	4.32
Government imposed payroll expenses	1.39
Union imposed payroll expenses	1.94
Hospitalization and medical	0.64
Equipment	19.06
Tipple	2.50
Hauling	1.87
Wheelage	0.13
Revegetation	0.21
Royalties	3.08
Direct taxes and fees	1.97
	\$38.50

Table 5. Net Profit After Expenses

Income for 450,000 tons at \$38.50 per ton	\$17,325,000.00
Equipment	-8,578,125.00
	<u>\$ 8,746,875.00</u>
Tipple, hauling, wheelage, revegetation	-2,118,750.00
	<u>\$ 6,628,125.00</u>
Payroll	-1,944,352.80
	<u>\$ 4,683,772.20</u>
Other employment costs	-1,790,117.14
	<u>\$ 2,893,655.06</u>
Royalties	-1,386,000.00
	<u>\$ 1,507,655.06</u>
Taxes and fees	-885,813.30
	<u>\$ 621,841.76</u>
Permits, bonding, engineering, construction	-621,040.62
Net Profit	<u>\$ 801.14</u>

In regard to hauling, a recently imposed diesel fuel tax of 6¢ per gal for highway vehicles will certainly find its way back to basic haul rates. This would increase hauling costs of the operation's total tonnage by \$1296.

Haul roads also vary greatly and the operator does not have a great deal to say about it. If this operator happened to need an extra mile of haul road, he would also happen to need an extra \$724,875 to build and maintain it.

And how about royalties? The rate in this situation was 8%. If it were 9%, the overhead would increase by \$173,250.

The most devastating change in operating costs is that of overburden ratio. In the operation described here, the ratio is 10:1. If that were 12:1, mining costs would go up by \$2,461,618.

SUMMARY

Using all the figures cited for the initial permit case, the total overhead for this operation comes to \$17,324,898.81.

Even this figure assumes no major problems in securing a permit, no prolonged work stoppages, average weather conditions, no unpleasant surprises with the coal seam, nor any other of the myriad problems which can plague an operation on a day-to-day basis.

With this overhead, the break-even price for mining a ton of coal is \$38.50. Table 3 shows how many tons of coal must be mined to pay for various overhead items. Table 4 shows the cost of these items per net ton. This price, \$38.50, does not include the charges for transport to the final destination, which could vary as widely as an in-state power plant to a Japanese steel mill. Selling the coal at the tipple will necessarily hold down the sale price.

Building in a standard profit margin for the operator will push the necessary sale price well past \$40 and probably past the operator's ability to market his coal. In other words, the bottom line here is that this coal tract, with no outstanding adverse conditions, can probably not be profitably be mined by the small operator (Table 5).

7.2.4 Powder River Basin Open Pit Coal Mines

WILLIAM E. WALESKI

INTRODUCTION

In the Powder River Basin, which contains over half of Wyoming's coal resources, mining conditions are unique. That is principally because the basin itself is unique. At no other place on earth is there such a combination of vast reserves and diverse conditions. Geological and topographic features are variable. Extreme weather conditions are common. Temperatures range from below -29°C (-20°F) in the winter to in excess of 38°C (100°F) in summer. Although the area is generally considered to be a desert, rain, snow, wind, and tornados are not uncommon. As new governmental regulations require innovative approaches, mining operations tend to be innovative. Some aspect of virtually every conceivable mining method can be found there. Even the workers in the mines are dissimilar. There are copper miners from Arizona, iron miners from Nevada and Minnesota, gold and silver miners from South Dakota, uranium miners from Wyoming, coal miners from North Dakota and Utah, and molybdenum miners from Colorado. There are farmers, ranchers, oilfield hands, teachers, lumberjacks, secretaries, and housewives. All this combines to create exceptional situations.

Basin Description

The Powder River Basin is a structural and topographic basin that covers more than $31\,079\text{ km}^2$ (12,000 sq miles) of northeastern Wyoming and southern Montana. It is bounded by the Black Hills to the east, the Bighorn Mountains to the west, the Hartville Uplift to the south, and the Missouri River breaks to the north. A more thorough description of the basin and its coal can be found in "Update on the Powder River Coal Basin" (Glass, 1976). The basin contains an estimated 544 to 635 Gt (600 to 700 billion st) of coal.

The geological conditions encountered in the Powder River Basin are quite variable. The coalbeds being mined range from 3 to 67 m (10 to 220 ft) thick. Some mines operate in a single seam while others mine multiple seams along with the intervening rocks. Often splits and partings are encountered. Dips vary from horizontal to 10° and intense local rolling is very common. Coal quality is wide ranging thus requiring diverse approaches to scalping and ultimately to mining itself.

Water inflow, both surface and subsurface, typically affects every mine in the basin to some degree. Powder River Basin mines tend to be of large areal extent, hence, they often intercept numerous local drainages and sometimes major stream tributaries. Also, the overburden, underburden, and the coal are usually all aquifers with differing hydraulic properties that are likely to change with both location and weather conditions. It should be noted that pit water not only affects blasting, excavation, and haulage, but also high-wall stability.

Often the full range of physical conditions can be found in a single mine. Environmental and regulatory constraints and the sundry responses thereto combine to further compound the diversity. Most of the companies represented in the basin operate or plan to operate at least two mines and it is interesting that no company operates both its mines in the same manner.

Mining Methods

The manner in which coal mining has been approached in the Powder River Basin is as discordant as the physical conditions existing in the mines. The only common denominator in Powder River Basin coal mining is that the vast majority of the operators utilize a truck-shovel combination to some extent. Besides the standard truck-shovel combinations, draglines, hydraulic excavators—both shovel and backhoe configurations—loaders, scrapers, Easy Miners, and one bucket wheel excavator are in use. Typically, this non-shovel equipment is used in conjunction with haul trucks.

One operator uses a dragline to recover the lower portion of the coal seam with the dragline sitting on top of the coal loads directly into haul trucks. This arrangement avoids operating any equipment on the extremely soft underburden. This, in turn, lowers the operating costs by eliminating excessive shovel setup and cleanup costs, additional haulroad construction and maintenance, and considerable wear and tear on the haul fleet.

Another operator uses *Easy Miners* in conjunction with truck haulage. This mine has extremely shallow overburden and consequently uses only scrapers and dozers for overburden removal. The coal is excavated by *Easy Miners* and loaded directly into trucks. Front end loaders are used as backup coal excavators. The *Easy Miner* configuration generates the potential for a continuous mining operation with the only restrictions being storage capacity for mined coal and the availability of trucks.

One bucket wheel excavator is presently in operation in the Powder River Basin and has been used to mine both coal and overburden as well as scoria for mine road surfacing material. In all of these applications it was used to load haul trucks. To date, this particular machine has largely been a failure and may, at least in part, be responsible for the poor reception that bucket wheels have had in America. However, it appears that its failure may well have been a result of misapplication by using too light a machine for heavy-duty work. Recently, however, this same unit has been more than adequate in excavating unconsolidated sand overburden and well shot coal.

As can be seen from the foregoing descriptions, the non-shovel excavators are typically used as shovel substitutes to load haul trucks. This is not to imply that draglines are never used in their original design application—to side cast overburden. It simply indicates a tendency in the basin to pattern all operations after the standard truck-shovel operations.

EQUIPMENT SELECTION PHILOSOPHY

General

In selecting mining equipment, the total possible combinations of equipment are many. The engineer should try to arrive at the best combination, even though that combination might be less than perfect. The engineer will need to exercise his best judgment in deciding when to abandon the pursuit of perfection in favor of advancing the cause of the best workable compromise.

Bias is often a major factor in engineering analysis. Opinions of how specific equipment will function in the operation

may or may not be based on fact. Occasionally, the information used to judge performance in the past may not be applicable in the present review. What worked under one set of conditions may not work under different conditions and vice versa. The engineer should strive to eliminate bias from the analysis—his own, his coworkers', his supervisor's, the manufacturer's—to produce a totally objective result. The best analysis will be the most accurate and honest one.

In a similar vein, even the most casual observer will notice that a piece of equipment liked by its operator will be more productive than a piece of equipment that is not liked. The actuality of this statement exists regardless of what the verifying numbers might indicate. No one has developed a simulation method that accounts for operator bias. If the operator does not like it, the unit will not work, and may experience an inordinate amount of downtime. Often, an operator's dislike for the equipment to which he is assigned stems from nothing more than the fact that the new unit differs from what he is used to. Here the engineer should include in his alternatives statements comparing the selection of lesser equipment to take advantage of operator preference with the selection of the optimum equipment, combined with a *selling* of the optimum to the operator.

There are occasions when management will choose something different from what the engineer's analysis indicated as the optimum selection. Management may have had access to additional or better information. They might even be making what seems to be an error. The engineer must remember that he is part of the management team, therefore, he might have to compromise his personal belief of what the best selection is in order to give management what that team feels it wants and needs. Although the engineer has a duty to provide his management team with the best advice and counsel, he also has a duty to the team and its decisions. At that point, he should make his feelings known—stating his position, all the available facts, and the reasons for his recommendation without belaboring any of them—and then support the team's decision. This can be a tremendous blow to one's idealism, but it is a necessary part of an engineer's development. Every engineer, at some point in his career, experiences this frustration. He may have produced his best analysis ever. He may even have produced the best analysis that has ever been done by anyone. Yet he finds his recommendations not being followed. It is a bitter pill to swallow. The engineer should remember three things above all others:

- 1) He is not the first person that this has happened to nor will he likely be the last. He is not alone in his frustration.
- 2) The fact that the results of an engineer's best work are not followed is in no way a reflection on him or his abilities.
- 3) Even the best study can be outweighed by someone else's 20 or more years of experience.

Keeping these things in mind will help the engineer to avoid bad feelings that can last for years and, ultimately, will aid him in his career advancement. Future experience will prove that teamwork is more important than an individual effort.

Generic Considerations

Before someone can select equipment, he will need to know what equipment is available and who the suppliers are. Likewise, in order to apply the proper equipment to given conditions, some understanding of those conditions and actual mining procedures must be garnered. Therefore, the mining engineer should make every effort to stay abreast of

the developments in his profession. Professional journals, conventions, and seminars provide excellent base data. Contacts with manufacturers and their representatives will generate more specialized information. The purchasing department can be a good source of information. Purchasing departments should circulate brochures on new equipment and even set up meetings with manufacturers for presentations on new products and developments.

The best information is, of course, hands-on experience. Enlightened companies provide ample opportunities for engineers to serve as front-line supervisors. As such, the engineer will be able to try some of his own ideas in the field and experience first hand the problems that are inherent in production. If the opportunity for hands-on experience is not available, the engineer should try to glean all the information he can as an observer. He should visit as many different operations as possible, both in his company and elsewhere. This is an easily accomplished task in the Powder River Basin where there are 20 mines within a 161-km (100-mile) radius of Gillette, WY. Interviews with supervisors, operators, and maintenance personnel will give insight into good points and bad points, likes and dislikes, and specific uses and limitations of various equipment types. Here again, the engineer should be aware of possible biases. As an observer, the engineer would have flexibility to determine the reasons for delays and downtime. He should time-study every aspect of the individual operations, paying special attention to ways to streamline procedures, methods for eliminating bottlenecks and delays, and to cost-cutting potential. As the engineer observes new and different techniques, he should remember that being different does not make something either good or bad. Furthermore, something that he observes as being less than ideal may be an outstanding producer when used in other combinations or other applications. Lastly, the engineer should try to determine if conditions exist at other mines in the immediate area that require special mining techniques. Those same conditions could exist at his mine and may well make an otherwise ideal piece of equipment useless.

Specific Considerations

The selection of equipment for a particular operation can be broken down into five steps:

- 1) Look at the property.
- 2) Look at the available equipment.
- 3) Generate a mining plan matching equipment to the property.
- 4) Develop alternative plans.
- 5) Pick the optimum alternative.

Looking at the property should include consideration of the size and configuration, reserves, production levels, material properties, regulatory constraints, and the possibility of expanded operations in the future. A general rule of thumb in the Powder River Basin has been that big production requires big equipment. Therefore, mines there have tended to try to field the largest equipment available. The results of this effort have largely been negative. Haul road materials lack the bearing capacity to carry the increased wheel loads. This results in bumpy roads, lower speeds, increased maintenance, lost production, and increased costs. Slightly smaller equipment with wheel loads that do not exceed the bearing capacity of the road materials may well alleviate problems while actually boosting production and profits. On the other hand, building better roads could also be a possible alternative. Another important aspect of equipment selection in the Powder River Basin is the ability to handle materials

selectively. Overburden of specific sand content is often selectively placed in the backfill in order to re-establish aquifers and reconstruct stream channels. Likewise, boulders are stockpiled for later use as riprap or rabbit habitat. This special handling sometimes requires special equipment.

Generating a plan that matches equipment to the property should include matching equipment to equipment. There has been a tendency of late to mismatch equipment. A good example of this is trying to load big trucks with small front end loaders. It can be done, but it is not very efficient. Another consideration is the problem of scale with regard to maintenance. Big equipment requires big tools to work on it and big facilities to house it. Furthermore, when big equipment breaks down in the mine, it must be repaired where it sits. This is an item of major concern in the Powder River Basin where winters can be very long and harsh.

The engineer will find that his attempts to reconcile the possible equipment combinations with all the possible conditions that can be encountered to be a monumental task. The best way to handle all the possible alternatives is through the development of production parameters. Production parameters are a quantitative tool for describing equipment capabilities. Typically, they are based on distance, time, speed, and capacity. Each make and model is so described. The interaction of various types of equipment is then studied to determine an optimum mining rate that agrees with the physical conditions at the mine. This is usually done through computer simulations. Units are matched that maintain the rate. Costs are then applied to further optimize the selection.

Each of us tends to see things in a specific manner. Our own biases get in the way of our creativity. The development of alternative plans forces one to look at things with a different point of view and with differing perspectives. Whereas we have a tendency to be protective of our ideas, it causes us to view other approaches more open mindedly. Quite often, a good plan can be made even better through the incorporation of aspects that by themselves seem less than adequate. Furthermore, working through an alternative solution will make a much more vivid impression than just casually thinking about it. Compromises will appear much more attractive.

It is important to bear in mind that tradeoffs often exist between capital and operating costs. A classic example of this exists in the Powder River Basin—the capital-intensive operating philosophy vs. the labor-intensive operating philosophy. Labor-intensive operations are characterized by comparatively larger workforces, higher equipment utilization, and lower capital costs. There is only one piece of equipment for each operator with only enough spare units to account for availability. Typically, the labor-intensive operations use some type of multiple-use truck to haul both coal and overburden as needed. Trucks can switch from dirt to coal, or vice versa without missing a load, thus providing flexibility. The capital-intensive operations are characterized by smaller workforces, lower equipment utilization, and higher capital costs. There are usually two or more pieces of equipment for each operator. Here flexibility is sacrificed in order to optimize specific functions of the operation. The capital-intensive operations typically run two distinct truck fleets, one for coal and one for overburden. The coal trucks are usually a large volume, bottom-dump truck featuring rapid discharge. This gives a larger payload and faster cycle times. Switching from coal to overburden necessitates changing trucks. Using a dirt truck on the coal haul sacrifices the larger payload and, hence, efficiency. Again, the choice between capital-intensive and labor-intensive operating philos-

ophies is one between optimizing specific mining functions and flexibility.

CAPITAL COSTS

Capital costs are those arising from the purchase of goods that are in turn used for production: buildings, plants, machinery, heavy equipment, etc. The only way to avoid capital costs is to not buy anything. No matter how small an operation might be, it will incur some capital expenditures. The objective, then, is to maximize the return on the investment. This return is a function of the interplay between both capital and operating costs. There are ways to reduce a mine's capitalization. However, they all will involve some sort of compromise.

Big Equipment vs. Small

The purchase of comparatively smaller equipment does effect a savings in capital cost. Small equipment, by virtue of its size, uses less iron and, hence, costs less. Bigger equipment is heavier, requires a larger engine, and burns more fuel. It also requires larger tires, maintenance facilities, and tools. On an hourly basis smaller equipment costs less to own and less to run. However, when considered on a production basis, the analysis becomes much more complex. Large equipment carries a bigger payload. Small equipment can cycle faster and thus carry more loads per shift. At this point, an analysis comparing specific equipment is necessary. Considerations should include:

- 1) What is the specific application?
- 2) Can the unit in question accomplish the task?
- 3) Are qualified operators available to operate the unit? Could some be trained? What would this training cost?
- 4) What is the total cost—both capital and operating—on a production (per ton) basis?
- 5) How will the unit be utilized in slack periods?
- 6) Which unit will be most beneficial in all respects?

An interesting analysis along these lines is presented by Kaufman and Bowen (1981).

Delayed Purchase

The concept of delayed purchase is based on the theory of time value of money, whereby a unit of money is seen to have more value today than it will in the future. Placing a property into production requires the expenditure of capital. Does this mean that all new projects should be delayed to effect a savings of capital? No, because money earned today has more value than money earned in the future when viewed in a similar light. The object, then, is to spend capital in such a manner as to maximize the return on the investment.

One method of achieving this goal is to mine on an increasing ratio strategy. Stripping ratio is defined as the ratio of the specific yards of overburden needed to be removed to the specific tons of coal production facilitated by the removal of the overburden. Now, by mining areas of low overburden first and gradually progressing into areas of thicker overburden, the stripping ratio will gradually increase, provided the thickness of the coal remains constant. This allows a minimum acquisition of equipment to take place initially. Furthermore, additional equipment is required bit by bit over a period of time. Ideally, a minimum of capital is being expended while production generates income at an optimum rate.

Another approach is to build part of a facility or develop part of a mine and then expand it later. Modern mining equipment is becoming increasingly larger and more complex. Extended periods of time are required for its assembly at the mine site. Experienced operators are unavailable; there-

fore, extensive training programs are required. Starting a project on a small scale provides several benefits. First, there is no temptation to attempt to assemble a large fleet of equipment all at the same time. Second, it facilitates training by making it possible to deal with new operators in small groups and on an individual basis. Third, it delays some of the capital spending until some time in the future while freeing up capital for investment in other projects now. This approach provides the opportunity for diversification while still furnishing cash flow. Furthermore, it allows, at least to a limited extent, a sort of trial use of equipment before commitment of the entire investment. Lastly, it makes problems more manageable—it permits them to be examined and solved while they are small and easy to handle rather than after the project grows to full size and complexity.

Elimination of Peak Equipment Requirements

Quite often, variable overburden thicknesses will require large volumes of overburden to be moved for relatively short durations of time. Similarly, periods of reduced overburden movement will also occur. This happens in the Powder River Basin even though coal production remains constant as the result of undulating surface topography. The typical mining plan analysis responds to these production changes by calling for adding and deleting equipment and personnel as production demands change. If equipment were to be acquired on the basis of this type of plan, periods of extremely high capital expenditure would be encountered. Likewise, after the production peak has passed, the excess equipment and personnel needed to handle the peak would be idled or operate at a reduced rate. Neither of these conditions is desirable. A better way to deal with variable production rates is to design so that a production level is maintained that averages the peaks and valleys. The overburden benches advance at a relatively higher rate prior to approaching areas of thicker overburden and the bench configuration expands. Upon entering the area of thicker overburden, the bench advance slows down and the benches begin to stack. As the area is passed, once again the rate of bench advance increases and the configuration expands. Acquiring the necessary equipment to attain the required production plateau may cause capital to be expended slightly sooner than otherwise desired. However, this avoids having to purchase excess equipment and then idling it later. Furthermore, adequate planning will insure that the early capital acquisition will be much less than that required for peak conditions.

Work Scheduling

The schedule upon which a mine operates can have a great impact on its capital equipment requirements. Some mines in the Powder River Basin opt to provide their workforces with weekends off. This five-days-a-week plan is a benefit to employees and also keeps overtime to a minimum. However, it does not make full utilization of equipment. Other mines schedule complete operations on seven days a week to take advantage of the total capacity of their equipment. Still other mines follow schedules somewhere in between. If two identical mines with the same size equipment are producing the same tonnage and one operates five days a week while the other operates seven days a week, the seven-days-a-week mine will be able to meet its production requirements with less equipment.

Operating schedules can be variable, from 5 days worked and 2 days off on straight shifts to 7 and 2, 7 and 2, 7 and 3 on rotating shifts even to 28 and 2. Also, they can be flexible on a daily basis. An overlapping system where the shifts actually change on the equipment instead of at the

change room can be very beneficial. Not only would this eliminate some of the lost production time associated with shift changes, but it would also improve turnovers with respect to the peculiarities of the individual equipment and the exchange of information on conditions in the mine. Tradeoffs exist involving employee attitudes and productivity and between capital and operating costs. The critical aspect is to get the maximum benefit for the money spent.

Contracting the Work

It may be possible to eliminate capital equipment by contracting various phases of the work. Where allowable under local labor agreements, contracting can remove the need for entire fleets of equipment. Furthermore, it excludes having to provide operators, maintenance, parts, and supervision for that part of the operation. In addition, payment is only for work that is actually done. There is no charge for idle or slack time. Finally, all the work is guaranteed—there is no payment until the work is right. An added bonus is the potential bargains that competitive bidding can produce. In the recent past, one Powder River Basin operator was having his topsoil handling done under contract for 40¢ less per yard than another operator could do it with his own equipment.

Warehousing

The items sitting on mine warehouse shelves can be a tremendous sink of expended capital. Parts for equipment no longer in service can sit there forgotten. Thus they create a demand for additional storage space that is not really needed. Parts for existing equipment that will never be needed could collect dust forever. Each represents money spent. No effort is made to delete unnecessary items from inventory and return them for credit. It should be noted that, in most cases, vendors charge a restocking fee of between 10 to 25% if parts are returned for credit. Here again a tradeoff exists.

Often, when a company purchases an altogether new piece of equipment, they will request a “list of recommended spares” from the manufacturer. All too often, every item on the list is stocked in the company’s warehouse. These lists are meant to serve as a guide. Typically they show each individual component item as well as assemblies. Stocking the entire list, then, results in duplication of supplies. Supplier’s warehouses have helped alleviate the problem somewhat. Prior to making an equipment purchase, it may be possible for the buyer to negotiate with the probable vendors to have the vendor agree to stock spare parts and supplies and specific quantities thereof. This would decrease capital spending for both supplies and warehouse space. However, breakdowns on off-shifts and the delays caused by having to wait for parts still generate a need for on-site warehousing. What is needed is a thorough analysis of each specific type of machine’s parts consumption. While some parts are consumed on an almost daily basis, others are virtually never needed. A probability analysis would indicate which parts and how many thereof would be kept on site. Less frequently used items would be left to the supplier’s warehouse. The warehouse stocking policy should be modified as needed on the basis of experience and the ease of obtaining nonstocked parts. The deciding factor should be economic expedience, that which generates the least ultimate cost.

Specific Mine Costs

As indicated previously, the Powder River Basin mines are typically truck-shovel operations. Total capitalization on a per mine basis ranges from \$50 to \$200 million. The shovels most commonly found are P&Hs 2300 and 2800 and Bucyrus

Erie's 295B. The most common trucks are Unit Rig's M-120-17 and MK-36 and WABCO's 120C and 170C Haulpacs. Approximate capital costs for shovels have been ranging from \$3 to \$5 million each and are about \$700,000 each for trucks. Capitalization for a Powder River Basin mine's physical plant can be quite variable depending upon office architecture and decor and the size of the equipment maintenance facilities. Capital costs for coal handling facilities vary with the type of storage and length of the rail loop. Silos cost around \$335 per ton of storage and slot storage systems are about \$230 per ton of storage. Unit train railroad loops cost about \$90 0.3m (per ft) of length while weigh-in-motion track scale systems are around \$900,000.

An additional source of capital expense is the mine permitting process. A new mine in Wyoming would probably need 150 individual authorizations including: an industrial siting permit; a land quality permit; an environmental impact statement; state engineer's authorizations; water quality permits; a solid waste permit; an air quality permit; and a permit from the Federal Bureau of Alcohol, Tobacco, and Firearms. Each individual water well, whether it be for mine water usage or just for monitoring purposes, requires a separate permit both from the state engineer's office and the Water Quality Div. of the Dept. of Environmental Quality. The air quality permit alone can take two years to acquire data and model potential dust emissions from the proposed mine prior to initial construction.

The most exhaustive of these permits is the land quality permit. It is divided into four parts as follows:

1. *The Adjudication Section*—A description of who owns what and copies of surface owner consents for areas both in the actual mine and adjacent thereto that will be overstripped or otherwise affected by adjacent mining.
2. *The Land Description Section*—A complete description of the land in its premining condition, its past uses, its present uses, and the current condition of all resources (soils, vegetation, wildlife, etc.) of the area to be mined. The heart of Wyoming's Environmental Quality Act is the requirement that all land disturbed by mining be reclaimed to a use equal to or greater than its premining use. Therefore information must be presented to answer every conceivable potential question.
3. *The Mine Plan Section*—A description of how the operation will affect resources both on and off the site. It details all activities associated with the extraction of coal and the movement of overburden and all activities that will be undertaken to protect, preserve, and minimize the impact on the environment.
4. *The Reclamation Plan Section*—An explanation of how the environmental resources of the site will be restored, reconstructed, or enhanced. This is done by identifying the post-mining land use and detailing its condition and how that condition will be achieved.

Now, what does it take to satisfy these requirements? Estimates for Wyoming's Powder River Basin mines indicate that a complete permit application requires the full-time efforts of six environmental scientists, two mining engineers, one attorney, two draftsmen, and two secretaries. In addition, up to four part-time temporary employees may be needed for proofreading, editing, folding, assembling, etc., of the physical data. This translates to in excess of 100,000 hr of labor and can range in cost from \$300 to \$800 per acre of land affected by mining. It should be noted that the permit application for the first major mine operating in Powder River Basin contained 2700 pages of text and 150 maps. The full-time contributors are still engaged in monitoring activ-

ities, updating and amending the permit, reporting on activities, and insuring that all aspects of the operation comply with the requirements of the permit. Also, the Land Quality permit must be renewed every five years. Therefore, almost as soon as work is completed on one, it must start again for the next submittal.

OPERATIONAL COSTS

Operational costs are those that vary with the rate of production and other conditions. They include the cost of labor, raw materials, fuel, power, and overhead. They are the costs most easily controlled by eliminating waste and inefficiency. In the Powder River Basin, these costs range from \$2 to \$5 per ton of coal produced. Where an individual mine's operating costs actually fall in this range will depend upon its production level and how the costs are viewed. That is, one mine may view a specific cost as a part of its capital expense while another mine will view it as an operating expense.

Cost Functions

Operational costs are usually broken down into or tracked on the basis of the functions actually being performed. The entire mining operation is divided up into separate distinct functions. The costs associated therewith are grouped and subtotaled in a similar fashion. The functional breakdown can be made as simple or complex as desired. Additional complexity maybe desirable as a means of tracking cost pass-throughs and as an aid in achieving cost effectiveness. Generally speaking, complexity beyond that which provides a direct benefit should be avoided. Increased complexity is typically achieved by a further breakdown of a more simple system. For example, a Powder River Basin mining operation could be divided on the basis of environmental, coal, overburden, and, where applicable, interburden functions. Each of these functions can be further divided, as shown in Table 1. Charges based on individual operating units can fall under headings in the table. That is, the cost of operating labor on a specific coal shovel would be subtotaled under III.B.1.a. or the cost of repair supplies for a specific dirt truck would be subtotaled under II.C.2.b.

Typically, the data collecting and storing process has been computerized. The shift foreman's daily time sheets or employees' time cards are the initial source of data for tracking functional costs. It would also be possible to use equipment cards or reports for this purpose. In fact, equipment cards could prove to be the best source of information as they also indicate time lost due to delays. Fig. 1 shows an explanation of one method of encoding the data for computer input. Again, the information being entered can be made more or less complex as desired. The first five columns provide a general description of an employee's daily work. The last four columns specify exact activities and the accounts to which they should be charged. Each activity or change requires an entire line to describe it. The total of the hours column for all the lines should equal the employee's total time for the day. Fig. 2 shows an equipment list with the respective codes to be entered in column 8 in Fig. 1. Fig. 2 also shows codes for miscellaneous labor not associated with specific pieces of equipment and codes for special accounts. It should be noted that a special account code replaces all of columns 6, 7, 8, and 9 without any portion of it being assigned to any specific column. In this respect it acts as a flag. Under this coding plan a spotter on an overburden dump would be shown as AC FA AAC.JJ B. A truck driver hauling overburden in truck 237 would be shown as AC AA

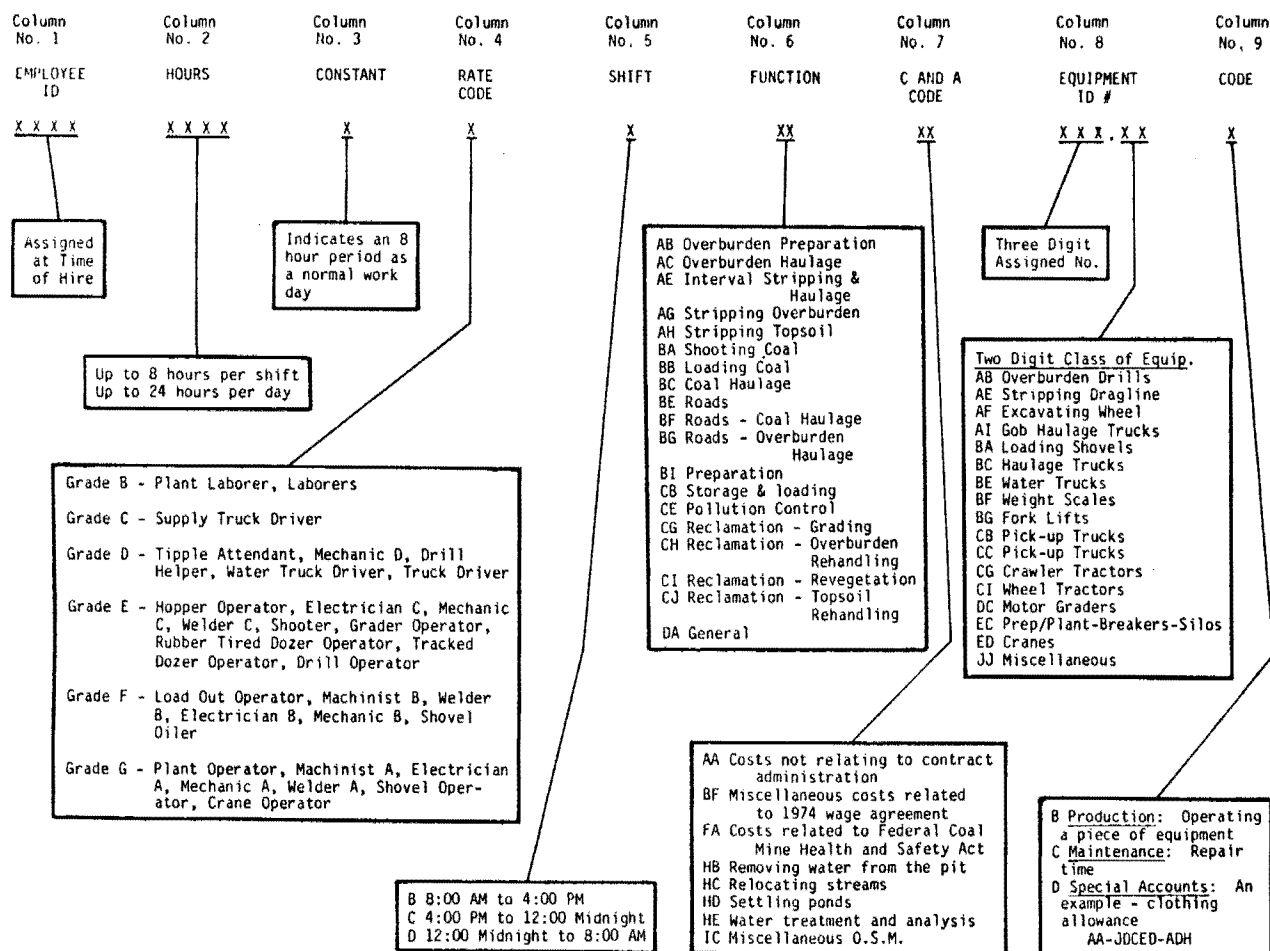

Fig. 1. Explanation of computer coding for functional costs.

CDH.BC B. Portions of the miscellaneous labor code numbers can also be combined to provide very specific descriptions of the work being done. For instance, a member of the pump crew who is repairing a pump used to remove water from an area of an overburden dump could be shown as AC HB ACE.JJ C. In these examples dumps are viewed as being part of the overburden haulage function. However, it would also be possible to add a separate item to the list in Fig. 2 specifically to designate work done on dumps.

With the system outlined previously, it is possible to examine and, hopefully, improve the operating cost picture for every aspect of a mining operation. The functional cost breakdown combined with data from operators' and maintenance reports (load count, delay times, type of delay, mileage, repair time, item being repaired or replaced, etc.) facilitate a very thorough analysis of operating costs. For example, the maintenance reports for a particular shift showing several broken haul truck hoist cylinders would be a definite indication of overloading. This type of cost analysis, combined with an enthusiastic, progressive approach to mining, allows a company to cut costs, improve benefits, and, at the same time, increase its profitability.

Efficiency Considerations

Good supervision can have a tremendous effect on decreasing operational costs. One of the most effective ways to reduce operating costs is by improved shovel staffing. Fig. 3

gives an indication of how a shovel's productivity is affected as trucks are added to the haul. Each additional truck increases the shovel's production rate until the maximum rate for the shovel is reached. In this example the maximum rate is reached when the sixth truck is added. After that, adding more trucks does not increase production. Each additional truck displaces another truck in the cycle and only adds to the queue. Theoretically, shovel productivity then decreases as more trucks increase the congestion around the shovel and interfere with the cleanup machine. Fig. 4 shows the effect on truck productivity of adding trucks to a single shovel. Here the productivity per truck remains constant until the capacity of the shovel is exceeded and then decreases with each additional truck. This is where good supervision comes into play. If the work force is of sufficient size so as to permit the start-up of an additional shovel through judicious use of personnel, the supervisor can effect an increase in production while actually decreasing the operating cost.

Fig. 5 again shows how shovel productivity varies with increasing numbers of trucks. In this case a second shovel is started after the sixth truck is assigned to the first shovel. The corresponding plot of truck productivity is given on Fig. 6. Fig. 7 shows the cost comparison on a unit basis for the two cases. Here the direct financial benefit of adding a shovel is readily apparent. Another way to look at this is on the basis of how production increases at a very minimal increase in total cost. Fig. 8 shows a comparison of how total cost

per hour varies with increasing numbers of trucks for one and two shovels. The additional increase in cost that occurs when the second shovel is started is the result of additional electrical consumption and the "upgrading" of hourly personnel. This cost is only about \$30 per hr in this example and is based upon actual time studies and operating costs. At the same time, production is being increased by about 283 m³/hr (370 cu yd per hr) for each truck added to the second shovel up until the capacity of the shovel is exceeded. This is predicated on the idea that both equipment and per-

sonnel are presently available at the mine site. Ownership costs for the additional shovel are charged against the scheduled production whether the additional shovel runs or not. Nothing is added. The supervisor just makes more judicious use of what he already has at his disposal. People are upgraded to run the second shovel. Cleanup machines and graders do double duty. Trucks from different shovels might haul to the same dump. Idle time and queues are eliminated. Everything meshes. The end result is that, on an incremental basis, the seventh truck hauls muck for less than 9¢ per yard,

Fig. 6. Truck productivity variation with increasing number of trucks. A second shovel is started after the sixth truck is assigned to the first shovel.

Fig. 7. Comparison of unit cost variations with increasing number of trucks on one and two shovels.

the eighth for less than $4\frac{1}{2}\epsilon$ per yard, the ninth for less than 3ϵ per yard, etc. It's like mining for free.

Please note that Figs. 3 through 7 also point to an alternative use of personnel. For instance, if there is only one spare person available on the shift, i.e., there are seven operating trucks on the first shovel described by the figures and no other hauls can be shortened to free up additional trucks, the operator of the seventh truck might be used for a special project. He could be used to man a dozer and build a ramp that ultimately would shorten hauls and allow the operation of the additional shovel at a later time. He could be used to

build a sedimentation pond. He could be used to set up an additional shovel for use on the next shift. Two or more trucks might make a longer haul that would equate to a standard cycle single truck haul. The possibilities are many. The better supervisor will find them and take full advantage of them to benefit the company.

Final Analysis

Mining, perhaps more than any other field of endeavor, presents opportunities for compromise. Different conditions, situations, and needs present different tradeoffs. The engineer

Fig. 8. Comparison of total cost per hour variations with increasing number of trucks on one and two shovels.

may find himself occupying this middle ground at any time. It might be trying to advance the cause of the best workable compromise or yielding to a team decision with respect to equipment selection. It might occur while trying to balance operator bias with the potential for increased production from new equipment. It could be in matching specific equipment to specific conditions in the course of optimizing some less than perfect plan. The balancing of capital and operating costs again offers the likelihood of reconciling alternatives. This includes the choices involved in big equipment vs. little equipment analyses, attempts to eliminate peak equipment requirements, and development of a warehouse stocking policy. Consideration of delaying a purchase or of different work schedules also displays inherent compromises. Finally, attempts to improve efficiency present a myriad of potential compromises. Should a longer haul be made now in order to facilitate shorter hauls later? Should extra employees be used on special projects or to boost production? Will avoiding a long haul now necessitate that it be done at some later time when trucks may not be available? Throughout it all, the engineer should strive to choose the alternative that will generate the maximum benefit to his company.

7.2.5 Base Metal Open Pit Mining

G. S. ZIMMER

INTRODUCTION

This section covers the fundamentals of methods used to estimate mine capital and operating costs for base metal open pit feasibility studies. Methodology is based on the combining of historical data with engineering and practical judgments to yield a best estimate of costs expected for a given mining plan.

A prerequisite for cost development is the generation of a mining plan and a resultant production schedule, which sequentially describes the flow of waste and ore material during selected time intervals. It should be noted that, while mine planning and cost development are sequential operations, they are also interactive as it is possible in many cases to reduce or to defer costs by revising the mine plan.

Following the development of a production schedule, the basic costing sequence consists of the following:

- 1) Determining production parameters.
- 2) Selecting mining equipment.
- 3) Developing equipment productivities.
- 4) Derivation of equipment requirements.
- 5) Developing a mine equipment capital and replacement schedule.
- 6) Calculating mine equipment capital costs.
- 7) Estimating personnel requirements.
- 8) Estimating mine operating costs.
- 9) Calculating mine capital costs including mine equipment, mine facilities, and preproduction operating costs.

Mine operating costs are developed by using equipment productivities to derive the number of shifts required to move a scheduled volume of material within a mining period. An operating cost per shift, in terms of maintenance labor, repair parts, and consumables, is developed for each type of equipment and is multiplied by the required shifts to obtain a total cost per mining period. Operating and maintenance labor requirements are based on providing sufficient manpower to yield the required equipment shifts plus related supplementary functions and these numbers of personnel are used to generate total labor costs per mining period. Repair parts and operating consumables costs are developed by utilizing the pertinent portions of the equipment operating cost per shift along with the respective number of required shifts to calculate a period cost. Mine overhead costs, consisting of salaried labor, salaried fringes, and hourly fringes, are similarly developed on a mining period basis. All period costs are divided by units of total material (ore plus waste) mined during the period to obtain a total unit cost and by units of ore mined to obtain a cost per ore unit that reflects the operating waste-to-ore ratio.

Operating unit costs are summarized by mining function (e.g., drilling, blasting, loading, hauling, roads and dumps, crushing/conveying, general mine, general maintenance, and general administration) with each function consisting of operating labor, maintenance labor, parts and consumables, and mine overhead.

A flowchart summarizing the development of mine capital and operating costs is shown in Fig. 1.

EQUIPMENT SELECTION

The equipment selection process consists of first determining the type of equipment required followed by deter-

mining the optimum sizes of equipment and the number of units required for a given production schedule.

The type of equipment required is a function of mine life, ore and pit geometry, site location, topography, and total material movement. A shallow ore body with a long life at a high tonnage rate may be most suited to a dragline stripping operation while a similar geometry with a short mine life may favor a scraper operation. A deep mine with a medium-to-long mine life and a high tonnage rate would probably favor a shovel operation, while a similar, but short-lived, operation would probably be more economical with loaders.

Once the type of equipment has been determined, the size and number required for each category must be determined. Equipment is usually sized as large as possible to comfortably meet production targets. The large equipment will take advantage of economies of scale and consequently will minimize unit costs, maintain the fleet at a minimum size, and will minimize labor requirements. Factors affecting or modifying equipment size include bench height, material density, ore selectivity, operating geometry, work schedule, and crushing capacity.

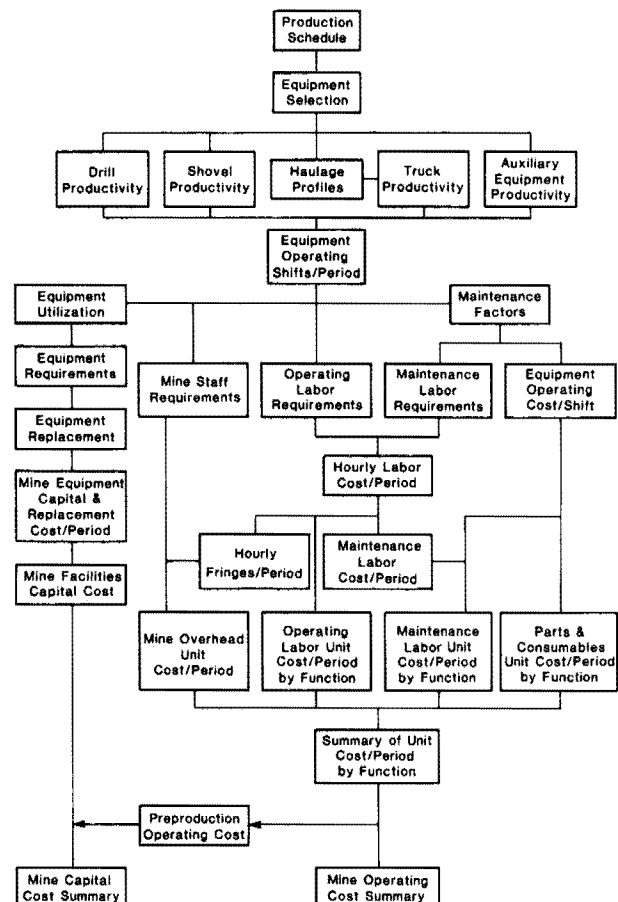

Fig. 1. Mine capital and operating cost flowsheet.

EQUIPMENT REQUIREMENTS

After the type and size of all major equipment has been determined, the numbers of units required for each period of the mining schedule are calculated by first developing a productivity per operating shift for each primary equipment category (drills, shovels, and trucks). Annual or period volumes are divided by these shift productivities to obtain the number of operating shifts required to move the material. The required operating shifts are divided by the number of

Productivity Per Operating Shift

Drilling productivity is a function of rock density, drilling pattern, and penetration rate. Rock density is either measured or estimated from specific gravity tables. Drilling pattern may be set by operating experience or estimated by various formulas based on hole diameter, bench height, subgrade depth, powder factor, and rock density. Penetration rate is either based on operating experience or on drillability tests. Average down-the-hole drilling time per 8-hr shift is normally 5.5 hr. However, this time is sensitive to bench height and penetration rate and a low bench height and/or soft rock will result in a lower drilling time per shift as more time is spent moving the drill from hole to hole. An example of drill productivity is shown in Table 1.

Loading (shovel) productivity is a function of rock density, swell factor, bucket size, bucket fill factor, truck size, truck load factor, swing cycle time, and truck spotting time. Material swell factor may be determined by actual measurement, estimated by comparison to other operations, or estimated from available tables. Bucket size is determined by machine size, material loose density, and range available from manufacturer. Bucket fill factor is a function of bench height and digging conditions and should fall within a range of 85 to 90% for well-fragmented material. Truck size is usually stated as a carrying weight in short or metric tons and trucks should be sized such as to be loaded in three to five passes from the loading equipment. A truck factor of 90 to 95% of rated capacity is normally used to prevent overloading and to exclude moisture, as the aforementioned densities are usually dry weight. Swing cycle time usually increases with equipment size and is a function of material density, digging conditions, swing angle, truck height, and operator proficiency. Swing cycle time may be obtained from operating conditions or estimated from manufacturer's tables or graphs. Truck spotting time is the time required for a haulage unit to be positioned under the shovel. Note that this time does not include truck queuing time or time waiting for trucks in an under-trucked operation. Spotting time may be minimized by using double-side loading. Table 2 is an example of a typical shovel productivity calculation. In this table, a shift is based on 350 effective min, which consists of a full 8-hr shift (480 min) less 60 min for lunch and start/end of shift delays less 10 min per hr for the remaining 7 hr to allow for operational delays. The number of truck loads possible per shift, assuming the loading unit is fully trucked, is the effective minutes per shift divided by the total time required

to load a single haulage unit. The resulting number of loads should be rounded down to the nearest full load.

Haulage unit productivity is a function of haul profile and truck speeds. Since haul profiles may vary considerably over mine life, truck productivity should be calculated for each mining period specified in the production schedule. To determine an average profile for a mining period, measurements are made from the centroid of each bench mined to the proper destination (crusher, stockpile, waste dump, etc.). Bench measurements include total horizontal distance, cumulative lift, and cumulative fall. To obtain an average annual or period profile, these bench measurements are weighted by the respective volumes mined. Maximum truck speeds for both loaded and empty conditions are determined from manufacturers' charts and are modified to suit project conditions and safety requirements. As most mines do not have passing lanes, truck productivity is effectively limited by the slowest unit and average speeds are usually less than the maximum allowed. Consequently, speeds in the vicinity of 90% of maximum allowed should be used. These average speeds are combined with the various segments of the haul profile to determine total travel time (loaded plus return) per unit, and a fixed time (queuing time plus spot and load time plus dumping time) is added to obtain total cycle time per load. Number of loads per truck operating shift is obtained by dividing 350 min per shift by the cycle time per load and rounding down to the nearest load. The number of loads per shift times the truck capacity times the truck load factor yields truck productivity per operating shift.

Equipment Operating Shifts and Units Required

Primary equipment operating shifts for each mining period are obtained by dividing the total volume of material mined in the period by the equipment productivities previously developed for drills, trucks, and shovels. Note that the foregoing calculations assume that the various mining operations (ore, internal waste, and stripping) required in each period are positioned such that equipment may be exchanged and substituted without a significant loss in productivity. In many cases, particularly when utilizing a pushback or phase mining system, operating geometry separates ore mining from waste stripping to the extent that these areas must be treated as separate entities for drilling and loading purposes, which will result in additional equipment. The utilization of the more mobile haulage units may be significantly increased to cover these situations by means of a computer truck dis-

patching system and to a lesser extent by radio dispatching. Examples of primary equipment calculations are shown in Tables 3, 4, and 5.

Mine auxiliary equipment consists of secondary drills (secondary drilling and wall control), front-end loaders (road maintenance and shovel backup), rubber-tired dozers (shovel cleanup), medium track dozers (dump maintenance), large track dozers (rip hard toes, road construction, and dump maintenance), road graders, and water/sanding trucks. Op-

erating shifts for auxiliary equipment are determined subjectively and are influenced by climatic conditions, length of road systems, number and location of working faces, rock type, and mining rate.

At this time, equipment requirements should be reviewed and the reasons for peaks identified. It is possible, due to adverse haulage configurations, for truck requirements to jump by several units without a corresponding increase in volume moved, which would not have been evident in the

20	12	12	0	0	0	0	0	0	2	10	0*

Note: When spare units occur, youngest units used first.

* Assuming a 20-year mine life, trucks should not be purchased during the last two years, if at all possible. At end of 20 years, the above truck fleet will consist of the following: two units, 6 years old; three units, 7 years old; six units, 8 years old; and one unit, 9 years old.

Metric equivalent: ton \times 0.907 184 7 = t.

mine plan. Should this situation occur, the mine plan should be reviewed to determine if advance stripping would alleviate the equipment peak.

MINE EQUIPMENT CAPITAL AND REPLACEMENT COSTS

To develop capital and replacement costs for mine equipment, the list of primary and auxiliary equipment is expanded to include support, service, and maintenance equipment. All items are assigned a replacement life that is a function of operating conditions, usage, and mine life. Table 6 shows typical replacement lives and example purchase costs for major mine items, excluding site-specific maintenance and electrical equipment.

Based on a given replacement life, a replacement schedule is developed for each item. These schedules are usually very simple to develop, but truck replacements can be complex when changes in fleet requirements do not coincide with replacement life. Table 7 is an example of a truck replacement schedule using the truck requirements developed in Table 5.

Initial equipment capital costs are calculated and a contingency of 10 to 20% is generally added to provide for a spare parts inventory. The costs of equipment additions and replacements are calculated for each mining year throughout the mine life. Note that equipment is usually purchased in the year prior to actual use to insure that units are available on January first.

In addition to mine equipment costs, capital costs must be developed for mine facilities including maintenance shops and equipment, crushing and conveying systems, explosives storage, fuel storage, electrical distribution systems, warehousing, offices, and mine access.

At this point, mine capital costs should be complete ex-

cept for preproduction operating costs, which are developed as part of operating costs.

OPERATING COSTS

As previously noted, operating costs are developed by using equipment productivities to determine the number of operating shifts required to move a given volume of material, followed by providing sufficient manpower, replacement parts, and consumables to cover the required operating shifts.

Maintenance Factors

As an integral part of operating cost development, factors have been developed that relate maintenance labor and repair parts costs per operating hour to delivered equipment capital costs. These factors have been developed by manufacturers and operators and are averages that will yield parts and labor costs within reasonable ranges. Factors representing average conditions for surface mining operations in the western United States are shown in Table 8. These factors are based on medium-to-heavy equipment usage in medium-to-extreme operating conditions. For use in other areas, particularly foreign operations, these factors must be adjusted to consider the effects of additional shipping charges, import duties, climatic conditions, maintenance skill levels, and maintenance labor rates.

Personnel Requirements

Mine personnel are usually subdivided into four main groups: (1) administration, (2) mine operations, (3) mine maintenance, and (4) engineering/geology. Salaried personnel in these groups are subjectively determined and, while providing adequate supervisory coverage, both job categories and numbers of personnel within categories usually reflect corporate policy and may vary considerably from company to company.

Table 8. Western US Maintenance Factors

Category	Class/Size	Maintenance Factors*	
		Parts	Labor
Drills	Diesel to 6.75-in.	0.0390	0.0252
	Electric 9-12.25-in.	0.0310	0.0170

Scrapers/water unitst	225-550 hp	0.0540	0.0360

* Used with delivered cost in thousands excluding erection cost.

† Factors applied to delivered cost less tires.

Metric equivalents: in. \times 25.4 = mm, cu yd \times 0.764 554 9 = m³, hp \times 0.745 699 = kW.

Hourly paid operating personnel must be sufficient to man the required number of equipment operating shifts per scheduled shift developed earlier. Using year 1 in Table 3 as an example, an average of 23.6 drill shifts per scheduled shift is required. To cover periods where more than the average of 2.36 units is available, a high average of 3.00 operating shifts per shift is assumed, which results in a total of three operators per shift times four shifts, equaling 12 drillers required. To provide for vacation, sick leave, and absenteeism (VSA), an allowance of 10 to 15% is added, bringing the total number of drillers for this period to 14. Operators are similarly calculated for shovels, trucks, and auxiliary equipment for each mining period, followed by a subjective estimate of support personnel (blasting crew, crusher operators, laborers, etc.). A more detailed method of determining major equipment operating personnel is based on the use of a binomial distribution to estimate the attainable equipment operating shifts per shift based on a given availability applied to a specific fleet size.

Primary maintenance personnel requirements (mechanics, welders, and electricians) are based on the number of equipment operating shifts per scheduled shift for major mine equipment and are derived for four maintenance areas (drills, shovels, trucks, and auxiliary equipment) by utilizing the maintenance labor factors in Table 8 to calculate a required number of maintenance shifts per operating shift. These maintenance shifts per operating shift are comprised of a proportion of mechanics, welders, and electricians that varies with equipment type and is based on historical distributions. Average maintenance shifts required per equipment shift and the distribution of mechanics, welders, and electricians for the southwestern United States is summarized in Table 9. Using a 154-t (170-st) truck as an example, the derivation of required maintenance shifts per operating shift is as follows:

Truck cost (delivered cost less tires and erection)	= \$ 759.0
Maintenance labor factor	= \times 0.0120
Maintenance labor, \$ per operating hour	= \$ 9.11

(Operating hours/shift)/(maintenance hour/shift)	= \times 0.875
Average tradesman pay rate (\$/hr)	= \div 12.00
Required maintenance shifts/operating shift	= 0.66

For each maintenance area, the numbers of mechanics, welders, and electricians are calculated as in the following example:

Shifts/man/year (42 hr/wk \div 8 hr/day \times 52 wks/yr - 5 holidays - 10 days vacation)	= 258
Drill operating shifts/year	= 2,554
Drill maintenance shifts/operating shift	= \times 1.25
Total maintenance shifts required	= 3,193
Mechanic shifts @ 60%	= 1,916
Welder shifts @ 10%	= 319
Electrician shifts @ 30%	= 958
Total mechanics	= 1,916/258 = 7.43 or 8
Total welders	= 319/258 = 1.24 or 2
Total electricians	= 958/258 = 3.71 or 4

In order to treat auxiliary equipment as a single maintenance area, an average number of maintenance shifts per operating shift is obtained by weighting the individual maintenance shifts per operating shift by the number of operating shifts in a typical year for each type of equipment. The average maintenance shifts per operating shift shown in Table 9 are based on operating these units as primary equipment. When these units are used as auxiliary equipment, the required MS/OS may be reduced by at least half, due to lower maintenance priorities, easier usage, and overlapping capabilities.

Hourly manpower requirements and the resulting cost per period for mine operations and mine maintenance are calculated for each mining period as shown in Table 10.

Operating Labor Cost/Ton

Operating labor costs for each period are accumulated by function and divided by the total tonnage mined during

* Includes 15% vacation, sick leave, and absenteeism (VSA) allowance.

† Annual rate based on 1928 hr at straight time + 215 hr of overtime to give equivalent time of 2250 hr per man per yr.

the respective period. Using Table 10 as a source, Table 11 summarizes the operating labor cost per ton.

Maintenance Labor Cost per Ton—Parts and Consumables Cost per Ton

The maintenance factors for parts and labor shown in Table 8 are used to develop an operating cost per shift (exclusive of operating labor) for each type of major operating equipment. In addition to these factors, relevant fuel, power, tire, bit, pipe, and stabilizer costs are also used. These calculations for drills, shovels, and haul trucks are shown in Tables 12, 13, and 14.

For each mining period, required operating shifts have previously been derived and are utilized in conjunction with the cost per shift and period tonnage to obtain the maintenance labor cost per ton for each function or equipment classification. In order to provide for unspecified maintenance (small vehicles, plumbers, carpenters, trainees, laborers, and miscellaneous), a general maintenance cost is developed by subtracting the cost per period for each equipment type from the total maintenance labor cost shown in Table 10. Table

15 is an example of maintenance labor cost per ton calculations.

The parts and consumables cost per ton is similarly developed for each mining period using equipment shifts and the respective cost per shift. In addition, the blasting consumables cost per ton must be derived, an allowance for mine utilities should be included under general mine, an allowance for gasoline and small vehicle maintenance should be included under general maintenance, and an allowance for general supplies should be included under general administration. Table 16 shows parts and consumables cost per ton calculations for the same mining period as the previous examples.

Mine Overhead Cost/Ton

Mine overhead generally consists of salaried and supervisory costs directly concerned with mining, the fringe benefits associated with these salaried labor costs, and the hourly fringes previously developed and shown in Table 10. Using the same mine period as in previous examples, assuming a salaried labor cost of $\$4,318 \times 10^3$ and 35% fringes, mine

Management and Organization

Donald O. Rausch, Editor

8.1 Introduction

DONALD O. RAUSCH

An integral part of any mining entity is management of the mineral, financial, and personal resources of the firm. Although management is not unique to this industry, managing the complexities of an efficient surface mining operation is certainly a challenging experience. This chapter gives the reader an overview into many of the primary considerations faced by various levels of mine management.

One of the paradoxes that everyone faces at one time or another is that corporate and middle management can often be at odds with each other. Theoretically all levels should be pulling together for the common good of the corporation, and yet major internal conflicts can tend to be the rule rather than the exception. These conflicts generally exist because each management level has different perspectives than do other management levels. For example, corporate management tends toward objectives that are longer-term, broad, idealistic and perhaps, even, somewhat ill-defined; their concern is for maintenance and growth of the corporation. Conversely, mine and other middle level management have objectives that are more precise and exacting, tending toward the shorter term; their concern is to keep the corporation solvent through production and sales, allowing for a future by keeping present business circumstances healthy.

More specifically, there has been a movement afoot since publication of the first edition of *Surface Mining* toward management involvement in *strategic planning*. Strategic planning impacts all levels of management, although the effort is most often initiated at the corporate level. This type of planning can be loosely defined as "where the enterprise is going and how it will get there."

Strategic planning is an especially useful tool in mining because the industry is very capital-intensive, experiences long paybacks, extreme cyclical swings, and has depleting assets. Strategic planning enables the mining firm to analyze its strengths and weaknesses to optimally develop its business. However, strategic planning is only a tool and is not a substitute for good management.

Good managers recognize their jobs as not just developing and applying policies and procedures but also as working with people—people with varying abilities and aspirations and with unique feelings and thoughts. Thus a major consideration in mining enterprises is management of human resources. Human resource management not only deals with such things as recruiting, selection, and compensation, but also with training and development, performance measurement, communication, and union/management relations.

While applying policies and procedures managers must

always realize one of their major functions is control. A well-managed enterprise is an active (not a reactive) entity; effective action can only be achieved through a well-maintained system of control. Critical to good financial control is effective reporting. Generally, the smallest responsibility area of a mining company's concern is the cost center. Cost centers are usually the operating, maintenance service, and administrative functions. Accurate and timely cost reports are imperative if these functions are to manage effectively; i.e., the cost control cycle must provide for an effective analysis of costs as they occur. Other important considerations are effective budgeting, procedures, and production reporting. All of these different facets should be integrated allowing for effective management analysis of the mining concern.

Too often individuals in mining tend to overlook, or at least, not to recognize the full importance of the sales and marketing of mined products. This is unfortunate because efforts expended toward marketing mined products directly impact the mining enterprise; i.e., sales generate revenues and without revenues no company survives for very long. Marketing is, however, more than just selling—it actually is the complicated interaction of four different functions: product, distribution, promotion, and pricing. This interaction touches on an array of ancillary specialties as well, and ultimately affects directly or indirectly everyone in the company.

In today's society the concern of permitting has become increasingly important for the mine operator. One piece of legislation which has had a major impact for many in the industry is the Surface Mining Control and Reclamation Act of 1977. Interpretation, compliance, and internal enforcement of this act usually comes under the realm of the corporate legal department. Close coordination between the legal staff and the mine operator can greatly reduce, or even eliminate, penalties as well as mitigate possible confrontations with federal inspectors.

Since management seems to be constantly faced with limited cash flows and high interest rates, it is even more important today that cost effective purchasing and inventory procedures be practiced. Besides these more traditional concerns, today's materials manager is now, more than ever, involved with such diverse things as the sizing and location of warehouse facilities to the complexities of information and data processing. Thus purchasing decisions, inventory management, storage, and maintaining spare parts can have a significant impact on the corporate bottom line.

A final major involvement by management is in govern-

ment and public affairs. Everyday more and more corporations are coming under close public scrutiny; presentation of a positive corporate image should be a top priority of management. Compliance with the myriad of relatively recent Congressional Acts is a necessity for any mining concern. Furthermore, it is imperative for mining firms to commu-

nicate to respective legislators their views on both existing and possible regulations; no one can better express the views of mining companies than the companies themselves.

The following sections will give the reader better insight into problems and solutions confronting all levels of mining corporate management.

8.2 Management Philosophies

CHARLES W. BERRY

DAVID E. FLETCHER

In addressing the issue of managerial philosophies and comparing ideas to determine if there are differences between corporate management and mine management, it can be stated that the first and most obvious difference is that corporate management is *goal-oriented* while management at the mine level is *objective-oriented*. The major differences between goals and objectives are that goals are broad, idealistic, not necessarily achievable phenomena, and relatively difficult to measure. An example of a corporate goal might be stated, "It is a goal of this firm to be one of the leaders in the industry serving the consumer with a high quality product, providing safe, meaningful, and secure kinds of work for its employees, while at the same time being a strong, secure, and high return investment for stockholders."

Goals are stipulated by policy statements and originate from the representatives of the ownership of the firm and the top levels of management. Goals are the things toward which activities are directed, but by their very nature are not specific enough to lend themselves to exact measurement. In the preceding example, as desirable as all of those things are that are suggested, there is very little that can be done to actually determine if any of those goals have been met.

Objectives on the other hand are specific, precise, exact statements of what is to be accomplished by the various elements of the firm. Being specific and precise, objectives can be measured in some commonly accepted and understood manner, such as, quantity produced, time to produce, or meeting deadlines and scheduled times. Unit costs should be measured in terms of final product from the operation rather than in terms of intermediate products, e.g., cost per pound of refined copper is much more meaningful than cost per ton of copper ore.

Objectives also must be supportive of the goals of the organization. One method of visualizing the relationship of goals and objectives is to view goals as parabolic in form and covering the entire range of activities of the firm, while objectives are the pillars or supports that maintain or hold up the parabola (see Fig. 1). Another major difference can be derived from this illustration; goals are representative of the totality of corporate activities while objectives are the ac-

complishments of individual parts of the organization. For example, every industrial organization has a need for some kind of production activity and a product or service. There is a need for some kind of marketing and distribution objective, and there is a need for finance, i.e., the development of financial reserves and resources and some method of allocating those assets. These are the traditional line activities found in any organization, regardless of size or complexity. If the firm is to achieve any degree of success it must achieve planned, predetermined objectives in each of these areas.

The well-managed firm will also have established methods and procedures for evaluating the achievements of the various parts of the organization. Included in this evaluation are the positions, functions, and personnel hierarchy related to the objectives supporting the goals of the firm (see Fig. 2). Concomitant with the evaluation process to determine the consistency of what has been accomplished with what was planned, a determination should be made with regard to the integration of objectives of various parts of the firm. The objectives developed by each part of the organization must not only be supportive of corporate goals, but must be integrated with and mutually supportive of the objectives of every other part of the firm. Extending this idea one step further, it can be seen that cooperation among the various parts of the organization is necessary if this approach to management is to be successful. Much has been said about the viciousness and cruelty of intercorporate battles over scarce resources. Whether these admonitions and caveats are true is not the issue, but what can be said is that the recognition of the objectives of various parts of the organization and the interdependence of these objectives is a viable way to develop the cooperation necessary for the success of the total corporate structure; Fig. 3 illustrates this interdependence. As can be seen, the structure can possibly survive the nonachievement of one objective or perhaps even two, but if others fail as well, the total structure will collapse.

The remarks in the preceding paragraphs are neither new nor startling; rather they are a brief discussion of the management style or philosophy identified as *management by objectives*. To summarize these ideas in the context of cor-

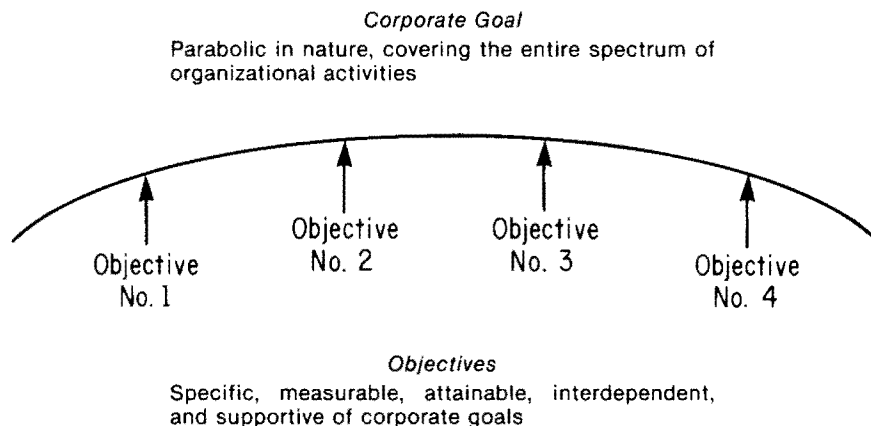

Fig. 1. Goal-objectives relationship.

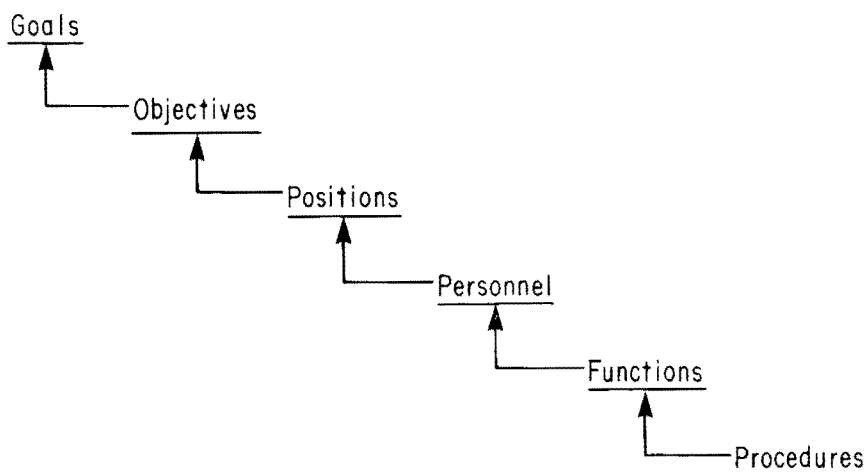

Fig. 2. Procedures-to-goals hierarchy.

porate goals and mine management, it can be seen that the corporate goals are supported by the objectives of mine management. In the mining industry, the production and operations aspect of the firm can be associated with specific objectives such as quantities of ore taken from the ore body, the grade of ore being recovered, the number of tons of ore delivered, at what cost, etc. The idea of management by objectives, then, seems reasonable for the mining industry. Further it can be observed that it is necessary to integrate the objectives of the operational aspects of the mining venture with the objectives of the finance element of the organization and the marketing objectives of the firm.

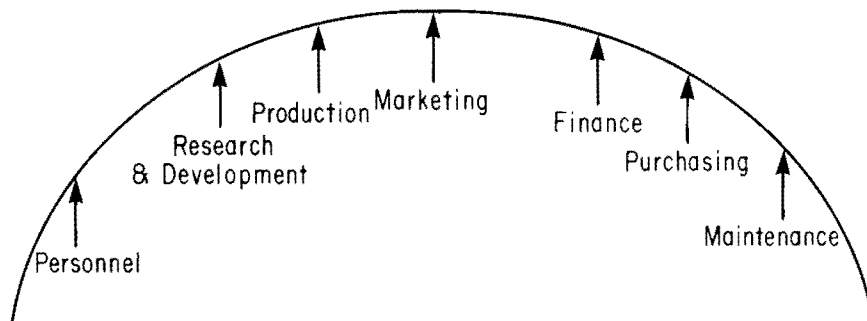

Anyone who is looking at corporate goals and the objectives of the various elements that make up the corporation can see that there is ample opportunity for conflict among and between departmental objectives, as each department has its own ideas about priorities of function and need for resources and rewards. A classic example in the mining industry is this: A corporate goal may be to provide the public with a needed natural resource without destroying the environment; on the other hand, a corporate goal may also be to provide a high return to the stockholders of the firm. Whatever procedure is selected to extract the minerals from the earth will have to be done recognizing the inherent conflict in these goals. Obviously there are methods of mining that are more destructive to the environment than others and these methods may be the most cost effective in terms of production. Other methods that may be less obvious and intrusive to the terrain may have significantly greater costs

associated with them with the attendant result of reduced earnings.

These policy decisions with regard to goals of the corporation will have a limiting effect on the objectives of various components of the organization. Mining operations will be limited in the techniques that can be used, the finance people will have to allocate resources of the firm based on whatever constraints the goals provide, and the marketing function will have additional limitations on the price that they can obtain.

Within the organization there are other potential conflicts. The production element may come in conflict with the finance and marketing components over such basic issues as who gets what share of resources in terms of money, manpower, equipment, as well as over issues such as authority, power, responsibility, and accountability. Consider the potential for different priorities in a situation where marketing wants materials available in certain quantities, at certain grades, and at a very specific time in order to meet the needs of a customer. To meet these demands, production management will probably have a case for soliciting more manpower, equipment, and funds from the financial managers. Finance will then find that to meet its objectives and to respond to the needs of the operating unit, it will have to require a higher price for the firm's product, which obviously again falls back on the marketing managers. Add to this the desire of operations managers to have the option of using what they perceive to be the most efficient and cost effective methods. They would like and need to have operations that are

Fig. 3. Interdependence of objectives to support goals. There is no significance to the location of the various functions in this model. Marketing, for example, is not at the top for any particular reason. The placement has been random, although an individual organization may wish to use this design to show priority of function.

safe and satisfying for their workers. These desires and aspirations may, although not necessarily, come in conflict with the finance managers who would like to invest as little as possible to obtain the highest possible earnings to investment ratios.

This discussion could continue for a much greater period than is devoted in these pages. The solution to these issues is to have an increased understanding of the problems and objectives of all the parts of the organization. It is difficult, if not impossible, for a manager of any phase of the firm to fully appreciate the position of another element of the organization if there is not a comprehensive understanding, not only of what other parts of the organization are trying to achieve, but also how the accomplishment of those objectives integrate with his or her own departmental objectives.

A final comment about the potential for intraorganizational conflict is that managers of the various elements of the organization, whether in the line functions of production, finance, and marketing, or in the traditional staff positions of personnel, research and development, purchasing, or whatever other staff functions may exist, must recognize that as much as they may wish to achieve their departmental objectives, they cannot do so solely at the expense of some other element of the organization. The result of this conflicting strategy is clear; the corporate goals cannot be jointly supported because some of the supportive objectives cannot be achieved and eventually the whole organization will fail. Good, clear communications among departments is essential for sound management.

Management in the mining industry has significant dif-

ferences from management in other industries. These differences are listed in Table 1.

Mining is very capital-intensive with investment in plant, property, and equipment normally single purpose; thus sound capital investment planning is essential. Market for product is derived demand rather than direct demand, e.g., the consumer purchases an automobile whose beginning raw materials are iron ore, coal, limestone, lead, zinc, copper, etc., rather than purchasing those mineral commodities directly. The remoteness of most mines is important in considering labor infrastructure and transportation. With mines, the ore reserve is finite; replacement ore bodies must be explored for and developed. Each mine is rather unique and each normally requires special engineering; in manufacturing and merchandising, many factories and stores are duplicates of each other.

The authors believe that it is important to highlight the differences between mining and petroleum. The commodity prices for most mining products are more changeable than petroleum products. In the exploration stage, petroleum normally requires large expenditures relative to total investment. However, in mining, most investment capital is in the development-construction phase rather than in exploration. In petroleum, once a reservoir is discovered, production lead time can be less than a year. Mining, on the other hand, requires several years for development and construction after an ore body is discovered. Because of the long pre-production period and changeable commodity prices in mining, timing of the development-construction-production sequence is financially critical.

Table 1. Differences Between Mining and Other Industries

	Mineral	Other
Investment	Most single purpose Highly capital-intensive	Many multipurpose Less capital-intensive
Demand	Mostly derived Little product differentiation	Both direct and derived Product differentiation
Location	Cannot move mine Infrastructure critical	Can select site Infrastructure minimized by site selection Can go to good labor
Raw Materials	Ore Reserve Time and money to find Difficulty in estimating Depletable	Purchase Multiple suppliers
Production	Each mine unique Variable raw material Extraction important	Similarity between operations Uniform raw materials
Differences Between Mining and Petroleum		
	Mining	Petroleum
	Exploration investment low relative to total investment	Exploration investment high relative to total investment
	Once reserve is found, long time (6 years) for feasibility, permitting, and construction	Once reservoir is found, short time (6 months) for construction (except some offshore)
	Relatively large construction investment	Relatively low construction investment

8.3 Strategic Planning

MILTON H. WARD

INTRODUCTION

Eric Hoffer states, "The only way to predict the future is to have the power to shape it." How to create this power is the subject of this section.

Business, or strategic, planning is the determination of where the enterprise wants to go and how it expects to get there. It involves the critical long-range thinking that assures fulfillment of the most important management responsibilities, survival and continued profitable growth of the business. Over the past few decades, a quasi-standardized method of strategic planning has been developed, generally accepted procedures formulated, and the practices of many companies reported in great detail. Specific programs and results of practitioners are well documented, and information on the subject has been reported in a number of excellent volumes and business publications. An intense interest in strategic planning developed during the 1970s; in the early part of the current decade (1980s), it was a highly marketable and profitable product for management consultants. Strategic planning now has its own special techniques, nuances, and lexicon, and its use in some form is considered a necessity for the progressive company.

Space limitations do not permit an in-depth review of all facets of this subject, but a brief description of the formal steps and techniques is required. Equally important are observations and opinions as to which steps are critical, and how these can be applied to the mineral industry. Both the techniques and the philosophy will be addressed, and in addition, a number of highly regarded books, texts, and resource materials are listed in the bibliography for those who desire to pursue this subject further. It should be noted early on that there are varying opinions on the merits of strategic planning; especially questioned is the value of the complex techniques of strategy development. This is a legitimate challenge, and while a host of practices are reported herein, all are not advocated. The wise planner will, as with any decision, review the options and select only those that fit his particular business and level of planning sophistication.

JUSTIFICATION

It has been said that few industries have a greater need for strategic planning than mining. This need results from the very nature of the industry: It is capital-intensive, involves long payback, is based on depleting assets (ore bodies), and usually deals in products that are inevitably battered by ever-repeating business cycles. Additionally, many of the parameters of the assets are unknown until the deposits are completely extracted. Former President Herbert Hoover, a renowned mining engineer and highly successful businessman, said of the business "... We must plunge in, learn, and repent. Not only is the useful life of our mining works indeterminate, but their very character is uncertain in advance."

Good business planning can do little to alter the size or shape of the ore body, but it can instill flexibility and prepare the company for change. Change will come as deposits are extracted. A mine experiences a life cycle similar to that of many other products, which in the parlance of strategic planning leads to a "planning gap" (Fig. 1). This term describes

the shortfall between desired sales and earnings performance of the enterprise, and what is more likely to occur if enough new earning sources (new mines) are not added to the company's asset portfolio. This gap develops because most products, industries, or mines follow a life cycle that results in a tapering off of earnings in the latter stages of their lives. Various terms have been coined to describe these stages as illustrated in Fig. 2. Development, growth, maturity, and aging are typical.

In mining, the *Development* stage is the period when the company is completing a mine and just beginning to produce. It is often characterized by low earnings, high debt, and small dividends. The next stage, *Growth* or *Expansion*, has good earnings, increasing output, improving efficiencies, and allows payment of dividends. This phase is followed by *Maturity*, when the design or high levels of production are achieved, operating costs are low, earnings are at a peak, and dividends are increased. The final stage, *Aging*, encompasses the period when earnings are decreasing and the product or mine moves into the twilight of its years. Mine operations in this stage are characterized by lower grade, poor efficiencies, and high costs, and if growth of the company is to be sustained, a new replacement operation should already be developed and production under way. Anticipating the need for additional growth, new mines, and a satisfactory mineral inventory, plus development of a plan for acquiring these, are tasks of the strategic planner. An example of how asset additions may be made to sustain growth is illustrated in Fig. 3.

Fig. 1. The planning gap.

Fig. 2. Product or mine life cycle.

Few companies, however, can show such an attractive growth profile, and even if a company is successful in finding and developing new mining properties, few can produce a solid record of increasing earnings. The upward trend is frequently thwarted by problems and delays in mine development and disruptions caused by the low phase of the business cycle. Independent analysis shows that the majority of new operations experience an extended time delay in attaining their design level of production, and that a high percentage of these have significant cost overruns. Such start-up problems, coupled with more frequent and deeper recessions and the increasingly difficult task of finding low-cost deposits, clearly challenge the objectives of increasing growth and earnings.

The history of free enterprise nations tracks a cyclical pattern, with expanding Gross National Product (GNP)

phases followed by periods of contraction (recessions). Producers of mineral and metal commodities are all too familiar with the problems that accompany recessions: increasing inventories and declining unit prices. Traditionally, the level of inventories has been a critical leading indicator of future activity in any business. Increasing stocks often portend a decline in prices, while a depletion of inventories forecasts a pick up in activity and higher prices. Unfortunately, producers are slow to accept the fact that a change is under way and that inventories are truly rising, particularly if the buildup follows an active, extended period of growth. When times are good, the tendency is to believe that the recessionary phase can be postponed, and when business is horrid, businessmen tend to think that the depressed state of affairs will never end. This feeling of either euphoria or overwhelming depression is understandable since commodity prices generally reflect either the nadir or peak of the cycle. But the cycle does repeat; at least it has twenty times since 1900 and eight times since World War II. In each instance, fortunately, the recession was followed by a period of recovery. Proper strategic planning should allow the enterprise to better prepare for, and react to, these changes. Proper planning requires certain conservative action to ameliorate the severity of the recession and wise investment and positive steps to capitalize on the higher-price periods that accompany or closely trail the boom phase of the cycle.

How well a company adapts to change, formulates its action plans, and develops new strategies for future growth will determine whether it survives and prospers. A good strategic plan can be an invaluable tool for guiding management, tempering optimistic projections, and reducing *seat-of-the-pants* decision-making. Granted, planning cannot eliminate the business cycle or place mineralization in a barren horizon, but it can indicate the trend of things to come and suggest methods for coping with the future. The case for formal planning is based on its ability to:

1. Encourage systematic management thinking.
2. Lead to better coordination of company efforts.
3. Foster controls and standards.
4. Force an identification of objectives.
5. Better prepare for unexpected developments.
6. Better define management's responsibility.

Strategic planning cannot solve all problems, but it will prevent many, and it can reduce the number of poor decisions.

TYPES OF PLANNING

Recorded history shows an evolution of planning over several millennia, ranging from the accomplishments of the Egyptians 5000 years ago and Alexander's exploits almost 2500 years ago down to the much-touted production and marketing achievements of the Japanese today. In recent decades, the strategic planning function has received an exceptionally large amount of attention, with a variety of classifications being formulated. The purpose of planning determines its classification and terminology, and often different management writers use different terms to describe the same type of planning. Also, purposes may blend or overlap one another, but practically all systems attempt to differentiate between strategic and operational planning.

Strategic Planning

This broadest or highest level of planning is concerned with the objectives and goals of the firm, where it wants to go, and how it expects to get there. It is under the aegis of top management and is principally concerned with the eco-

Fig. 3. Extending earnings life.

conomic, financial, and technical aspects of the business environment, with particular attention given to the future of the enterprise.

Operational Planning

This form of planning is involved with short-term aspects of the business, and unfortunately, it often consumes most if not practically all of management's planning attention. It is concerned with maximization of return and problems of budgeting, scheduling, monitoring, and controlling the daily or short-term (one to three years) activities of the firm.

Demarcation of strategic and operational planning is not easy or clear-cut, and classification is further complicated by the use of additional terms and definitions. Tactical (means and goals for attaining objectives), year-to-date (budgetary or shorter-term), and administrative (combination of staff and operational) planning are terms that further define and circumscribe the types of planning.

There is also a diversity of planning concepts or systems that incorporate the total range of planning, and a good example is shown in Fig. 4 (Stanford Research Institute). This formidable-looking flowsheet incorporates most of the plans required by a major business entity.

STEPS FOR DEVELOPING PLAN

Development of the strategic plan follows certain steps that are common to all types of business. These steps may be separated into four major categories:

1. Appraisal of the company:
 - a. Analysis of its markets and products.
 - b. Analysis of its strengths and weaknesses.
2. Formulation of mission and objectives.
3. Development of strategy.
4. Implementation of strategy.

The first step involves a determination of where the company is; the next, where it wants to go; the third, how it is to get there; and finally, the actual implementation. The appraisal, sometimes called the *situation audit*, is undertaken to identify and analyze the company's performance to date, its current situation, and its key trends. Here, the strengths, weaknesses, and opportunities are identified and existing markets and products are thoroughly reviewed.

MARKETS AND PRODUCTS

One of the primary objectives of the enterprise is to meet the needs of the customer, and it is therefore appropriate that the appraisal begin with an analysis of these needs. In making this analysis, a checklist of marketing and product questions should be prepared, and thoughtful, realistic answers developed. The questions should be tailored to fit the business under review—obviously, a consumer products company is different from the metal miner—but surprisingly the questions can be similar. The following might be typical:

Who are our customers?

How are the customers geographically distributed?

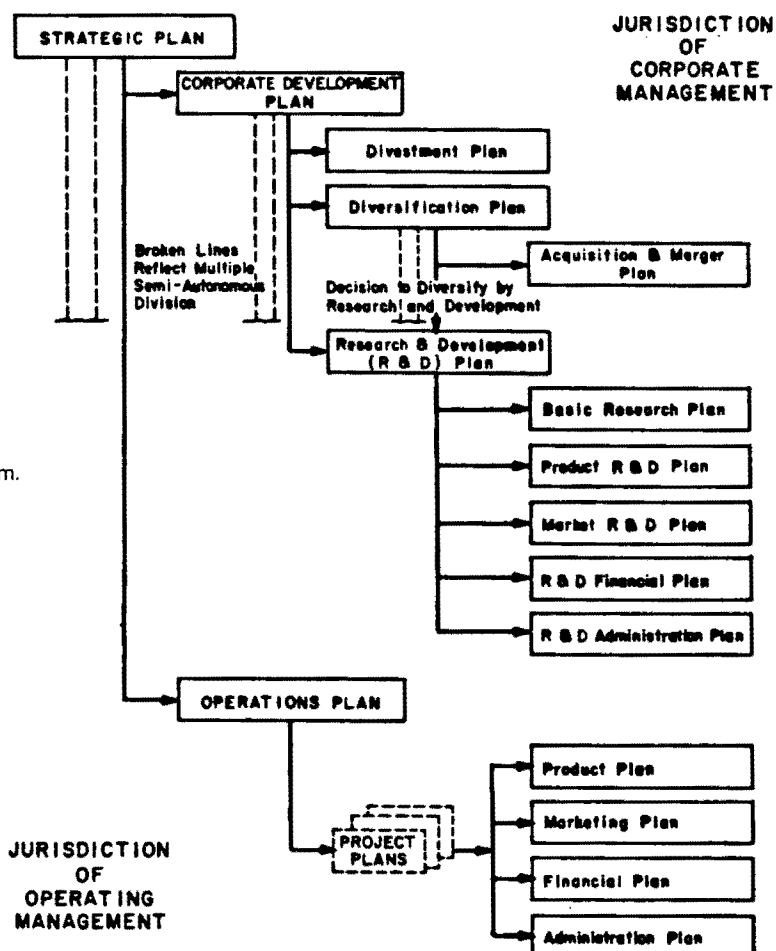

Fig. 4. Stanford Research Institute planning system.

Is the market developing, growing, maturing, or aging?
What is our market potential?

What percent of the market do we now have?
What is our cost position relative to other producers?

Is the market highly seasonal? Highly cyclical?

Is the market dominated by a few companies?

How difficult is entry?

What are the key factors with regard to competition;
price, quality, or service?

What is the role of foreign competition?

Is there unrestricted entry to our market by foreign competition?

Is the need for our commodity expected to change in the near term, next decade or two?

Undertaking a thorough analysis of markets and the competition could be a new experience for the typical mining company. Indeed, observers often criticize the mining industry for not giving sufficient attention nor applying creativity to this important facet of the business. The appraisal should consider the questions tabulated above and the answers to these, plus a rigorous assessment of other marketing factors, all of which could well lead to new strategies. Creating a demand for a specific commodity, such as copper, is no mean task, since by the definition of commodity, one pound of copper is identical to a pound produced by the competition. The innovative marketer realizes that he must sell more than just copper. The sales story must contain a host of benefits, including the company's ability to provide:

A reliable supply of the metal.

Timely transportation and delivery.

An acceptable sales price.

Pricing flexibility that may involve discounts, premiums, back-pricing, or other methods that meet the needs of the customer.

Similarly, the customer should be made aware of the company's technical competency, high productivity, large ore reserves and ability to find more ore, and its capacity to fund the needs of the operation. The company's expertise in the futures market and how this special knowledge can work to the benefit of the customer should also be explained.

This tabulation of marketing factors will be helpful in both identifying other opportunities and in focusing on problems. The list is not complete, but answers to these questions can be quite sobering. A US copper miner making this appraisal prior to the 1981-84 recession might have seen a mature industry, easy entry, a true product commodity that can be readily produced by many other companies, and one susceptible to substitution. And maybe he would have been surprised to find that his cost position was dangerously high—in the upper 25th percentile of world producers. Analysis would also have shown that lower-cost foreign competition can easily enter and capture his market, that copper is the basic foreign exchange generator and employer of foreign competitors, and that this competition will maintain its production even when copper prices drop precipitously. Last, and perhaps most important, the US copper miner would have noted that copper is an exceptionally cyclical commodity with a price greatly affected by the business cycle. This appraisal should call for action; possibly action to make the company more competitive or steps to lead away from copper and into more recession-proof businesses.

ANALYSIS OF STRENGTHS AND WEAKNESSES

"He is a fool who tries to match his strength with the stronger," warned Hesiod. Determination of when and where to make the match depends on knowledge; this is why a

review of the firm's strengths and weaknesses is critical. The review stimulates thinking and influences components of the plan. Needless to say, an honest, objective appraisal, like any self-analysis, is difficult to make. Often we magnify our strengths but must search for our weaknesses.

Strengths

The purpose of ascertaining the strengths of the enterprise is to identify areas in which protective action plans can be built. This review should cover financial, operating, personnel, and other assets, including special talents, patents, and facilities of the company. A listing of strengths for a diversified mining entity might include:

International operating experience.

Worldwide shipping knowledge.

Experience in the formation and operation of joint ventures.

Skills in managing low-cost mineral and metal operations.

Extensive reserves.

Marketable, workable patents for recovering byproducts.

Excellent, well-staffed research and development facilities.

A high quality, well-established mineral exploration team.

Exceptionally competent financial and legal groups.

A young, experienced management team.

A good cash flow situation.

Additional borrowing capacity.

Weaknesses

A French maxim notes that "One always knocks oneself on the sore place." It is amazing how weaknesses often manifest themselves at an inopportune time. A thorough search can identify sore spots and allow development of plans for overcoming or minimizing these. Shortcomings of the enterprise depend on the particular company, but a tabulation might show:

Diversity of products and markets is lacking.

High percentage of revenues flow from commodities.

Participation in only cyclical businesses.

Little influence over sale price of products.

Significant foreign investment exposure.

Poor record of projecting metal and mineral prices.

Limited marketing expertise in specialty minerals and metals.

No experience in making acquisitions.

Limited experience outside natural resource field.

Stock value unrecognized in the marketplace.

A thorough ongoing appraisal and critique of strengths and weaknesses usually expands these lists and often turns up unexpected additions—many favorable but some that merit corrective action. This phase of the planning process may justify the retention of an outside consultant or independent third party to assure objectivity.

CORPORATE MISSION

One of Webster's definitions for the word *mission* is "... a ministry commissioned by a religious organization to propagate its faith." This definition closely parallels that of *corporate mission*, which is the idea or statement that sets forth the direction and faith of the enterprise. Simply stated, a company's mission denotes the nature of its activities or the lines of business in which it will engage. Formulation of this statement requires profound thinking since it is the most important decision that senior management will make. "What is our business and what should it be?" must be asked at the inception of the enterprise and throughout its existence;

answering this is the primary responsibility of top management. The highly regarded management consultant, Peter Drucker, states that every great business builder from the Medici family and the founders of the Bank of England down to IBM's Thomas Watson had a definite idea and a clear theory of the business that was to be pursued.

Once determined, the mission can be conveyed to the organization and used as its guiding beacon. Some companies distribute their written charter to their constituents—management, workers, customers, and the public. Setting forth the mission in writing is recommended, and the practice is becoming more common, but many corporations still choose to guard this information from all except those who have a need to know. Other firms have no written mission—this is cloaked in the mind of the CEO, and he only metes out this information as required. He believes that secrecy restricts the flow of data to the competition and thwarts criticism or discontent from those who might hold different views about the future direction of the firm.

However, on balance, most would support articulation and distribution of the mission statement, if not externally, then at least within the organization. The advantages are several, including motivating top management to analyze the business and to actually think through and formulate the mission. It also provides a consistent, coordinated guideline for internal planning and actions, and informs the shareholder of the company's business so a more knowledgeable investment can be made. The mission statement can be brief or lengthy; it may speak only to the business with which the organization is charged, or it can be a meld of business purposes, aims, and philosophies of operation. Examples follow.

Actual Case—A Major Technical Corporation: "Texas Instruments exists to create, make, and market useful products and services to satisfy the needs of our customers throughout the world. Because economic wealth is essential to the development of our society, we measure ourselves by the extent to which we contribute to the economic wealth—as expressed by sales growth and asset return. We believe our effectiveness in serving our customers and contributing to the economic wealth of society will be determined by our innovative skills."

Actual Case—A Major Natural Resource Company: The following are excerpts from the company's annual report which outlines a portion of this entity's mission and businesses:

"M.I.M. Holdings Limited (MIM) is a mining and mineral processing company . . . its principal activities are: . . . Mining of copper and silver-lead-zinc ores . . . Refining of Mt. Isa's copper . . . Refining of lead and silver from Mt. Isa . . . Mining of coal . . . Transporting and stevedoring . . . Trading in nonferrous metals . . . Recycling of scrap lead . . . Exploration for base metals, coal, iron ore, gold, and uranium . . . Exploration for oil and gas . . ."

The public document from which this information was taken also notes the goals and major operating strategies of the enterprise.

Hypothetical Example—A Mining Company: "The Red Metal Mining Company is in the business of mining and milling copper ores."

Every business has its mission, whether it is stated in lofty inspiring words or only lightly etched in the mind of the CEO, and the entity that gives thoughtful attention to this is more likely to be satisfied with the results of its labors than the company uncertain of its reason for existence.

Objectives

Writings of strategic planning often include the words *goals* and *objectives* as though they were synonymous. In some companies they are, but in others *goals* are considered to be more short-term and of less importance than *objectives*. Generally, objectives last for years and relate to the broad issues of the enterprise, such as growth, profitability, stability, and image, while goals are more specific, focus internally, and are often more limited in duration.

The objectives which the organization seeks in order to fulfill its mission must be consistent with the fundamental purpose of the enterprise. Each objective should contribute to the mission, aid in decision-making, and give direction to operation of the firm. Objectives, which should be written, must be operational and serve as action guides for all critical areas of the company, and they must be conveyed clearly to those charged with achieving them. They should be challenging but attainable. The likelihood of fulfilling objectives should be reasonable, and in actual practice they are often designed with a 50% probability of success.

The following is an example of objectives that were developed several years ago by a major chemical and consumer-products company:

- Maintain a minimum annual growth in earnings of 10%.
- Raise dividends in line with earnings.
- Reduce interest-bearing debt to 45% of total capital.
- Increase the return on beginning-shareholders' equity to 18%.

Periodically, management of the company has reported its performance and success in achieving these goals, and to date exceptionally fine results have been communicated. Obviously publicly advertising objectives can lead to embarrassment if severe shortfalls occur. However, to be effective, objectives must be developed, discussed, and distributed internally, and many believe that giving public attention spurs performance and is well worth any loss of face that might accompany a shortfall in performance.

The objectives listed above relate to financial activities, and this sector of the business is critical, especially since survival requires profit and maintenance of a solid financial base. Therefore, it is appropriate that dollar-defined objectives be developed and pursued. However, formulation of goals should not cease at this point. Attention should also be given to social objectives and every facet of the business important enough to be the subject of planning.

Strategy

The action plans and programs undertaken to achieve corporate objectives are termed *strategies*. This is one of many similar definitions of strategy, and a few others are: 1) Strategy is the method whereby corporate objectives and goals are to be attained by the allocation of resources to activities; 2) Strategies consist of major action programs used to achieve missions and goals, and simply stated, 3) Strategies are how we get what we want. Objectives can be achieved in a variety of ways, but each method or path consumes resources of the company, and the path selected constitutes its strategy. The development of strategy requires a tabulation of many possible activities that may fulfill or meet the company's objectives, and then selection of those that can be afforded and which are most likely to lead to success.

It is apparent from earlier comments that the language of business planning is not without dispute. One writer's *mission* may be another's *objective* and one's *objectives* may be another's *goals*. A similar conflict exists between *strategies* and *tactics*, and in some writings the two words are syn-

onymous. In others they are distinctly different, with *strategies* being developed first and *tactics* being the action taken to implement the strategies. As an example, a firm may have a strategy to enter the gold mining business by acquiring a smaller company that holds undeveloped gold properties. Its tactic could be to purchase the smaller company by the use of stock rather than cash. Understanding the specific definitions of planning is important, but grasping the concept and having the ability to formulate and implement it is critical.

The first step in setting strategy is identification of activities that the company should consider undertaking, followed by selection of actions that are more likely to facilitate achievement of company objectives, allocation of resources to the selected activities, assignment of responsibilities, and fixing a time schedule for action and completion, and finally, identification of measures to be monitored in assessing progress. Strategies, like objectives, should be developed for every key area of the business. The selection process involves an assessment and decision as to whether to formulate new strategies or to maintain or drop old ones.

Methods for developing strategies are numerous and diverse, and generation of new concepts is an ongoing activity in this field. Management consultants find this to be an attractive area for marketing their services, and many have created sophisticated models for identifying opportunities. Among these are portfolio strategy, product-market matrix, research and development possibilities, and a host of other methods.

Portfolio Strategy—This method utilizes special categorized information to guide strategic growth decisions. The concept, which is based on the relationship of market share to growth for different businesses, was developed by The Boston Consulting Group. It uses a matrix that consists of four quadrants as shown in Fig. 5.

Here, consideration is given to the product's many characteristics, including its profits, cash flow, and market po-

sition. Based on this information, the product is assigned to one of the four quadrants. The Boston Consulting Group termed the quadrants (and the products in them) *Opportunities?*, *Stars*, *Cash Cows*, and *Dogs*. *Opportunities?* is the title given to Quadrant 1 because it supposedly has potential to capture a large share of a rapidly growing market. The second quadrant, *Stars*, is so named because it encompasses the best performers which "have a large market share in an increasing market." *Cash Cows* in Quadrant 3 reflects the divisions or products that supply funds for Quadrants 1 and 2. *Dogs* is the term given to divisions and products that are lodged in Quadrant 4. These are the worst performers that have no obvious chance for improvement. In addition to the quadrants, the matrix contains circles located in the various quadrants, and the relative size of the circles represents the product's assets or its annual volume of output or level of sales. Matrices of all or a selected group of these elements are assessed in determining the prospects of a particular product, commodity, or business.

The portfolio terminology and method of analysis has been in vogue for several years, and can be helpful in analyzing a particular strategy. As an example, a company may choose to divest itself of the *Dogs* (perhaps a nickel operation) and use these funds for additional investment in *Stars* (maybe gold operations) and *Opportunities?* (possibly silver operations). This method of appraisal also forces a review of the relative importance of divisions, and if considered over a period of time, it indicates progression, or lack thereof. Is the *Opportunity* division really moving toward a *Star* or is it stagnant? Are the *Dogs* beginning to cost too much to retain, and are their markets declining? These and other important strategic questions can be partially appraised by reviewing the company's portfolio, and such analysis may be helpful in the development of a more attractive strategy. The method, however, is not without drawbacks, and many of its shortcomings will be discussed later.

Research and Development—Recently, the advantages of R&D have been the subject of many technical conferences, seminars, and discussions in industry and government. This activity can indeed generate new products and suggest strategies for expansion, and it is the primary growth base for many companies, especially those in the chemical, pharmaceutical, and electronics industries. Similarly, the R&D effort of mining companies can lead to growth opportunities. New processes can advance the viability of low-grade mineral resources, increase the recovery of values from tailings, and allow extraction of additional elements from a given ore. Examples include pelletizing lower-grade iron deposits to create a source of iron ore, development of new reagents that lead to higher recovery in flotation, and piloting of more sophisticated processes that allow recovery of uranium from phosphoric acid streams. Additionally, R&D generates new opportunities by allowing the company to market and license new technology.

Monitor the Competition—Observing activities of the competition is a worthwhile practice that should be followed by all organizations, especially the smaller company. An ongoing review of others can provide information on marketing, R&D, and operating methods and techniques. This approach is especially helpful when considering entry into a new business. Many corporations have made the decision not to try to be Number One (or maybe not even Number Two) in pioneering a new business. They prefer to participate later, after the entry risk has been reduced. The decision of a company to be the initial participant in an industry is greatly influenced by its attitude toward risk-taking. Some

Fig. 5. Industry growth—market share.

mining companies would place seabed mining in this high-risk category. They believe the initial cost and risk level is too high, but they stand ready to try to carve out a niche if the competition is successful in its endeavors. This approach, which requires close monitoring of the competition, is also commonly used by explorationists. Here, the high cost of drilling a new risky area is avoided, but if the pioneering company is successful, the alert geologist moves in to stake around or adjacent to the area being drilled. This delayed-action strategy has advantages, but obviously it can also result in lost opportunities.

Soliciting Suggestions—The quest for new growth strategies can be extended out past top management and the formal planning group to include all members of the organization. This practice involves an explanation of the need for new ideas, followed by the use of the simple suggestion box. It is reported that this is a creative mainstay of Japanese industry, yielding one million suggestions for Toyota over a two-year period and resulting in savings of \$250 million. Solicitation of employee ideas is still used extensively in the US, although in recent years the practice has waned in the mining industry.

Opportunistic Approach—Some companies prefer to wait alertly for Lady Luck to bring opportunities. The follower of this approach argues that the cost, risk, and effort required to force its way into a particular market at a specific time are too great. It chooses to maintain its financial and technical competency and be poised to act when the appropriate opportunity arrives. Disraeli's words that, "Everything comes if a man will only wait," are indeed appropriate for this tack. As an example, such a mining company would not identify a product or commodity for development, but instead would just wait for an attractive property to come to its attention. In instances of this type, the copper miner that desired diversification would make no decision to enter a particular business, but would consider gold, coal, or any favorable prospect that became available. This has been a rewarding strategy of the well-financed company, allowing it to purchase underpriced assets and operations during the heart of recessions. Also, this opportunistic approach has led to acquisitions by *white knights* that came to the rescue and acquired or merged with companies being pursued by unwanted suitors. Obviously there are disadvantages to this practice, the primary one being the inability to dictate the time and manner in which action and growth are undertaken.

Intuition of Top Management—Intuition is the power or faculty to attain knowledge without rational thought and inference, or simply stated, a quick and ready insight. This is a method, or at least appears to be a method, frequently utilized by CEOs in arriving at growth strategies. In many instances this practice, which is about as simple as possible, yields excellent results, leads to major new businesses, and has been the foundation for growth for a number of major corporations. However, in other instances this practice has led to decisions and investments that have been disastrous.

Strategy Selection and Action Programs

Huxley advises that, "The great end of life is not knowledge but action," and if results are to be attained, action must be taken. In industry, implementation of action plans can commence only after the strategy is fixed, and this should involve rigorous decision-making and detailed analytical appraisal. Reviewing current strategy is a good starting point, and in doing this, the planner should ask:

What is our present strategy?

What trends suggest future change?

Which portions of our strategy are still appropriate?

Which activities should be dropped?

Which should be altered? When? How?

It is possible that existing strategies should be abandoned if, for example, it is apparent that the program will fail for technical reasons (ore reserves are found to be lower grade or the new revolutionary process will not work), financial reasons (capital or operating costs for the business are going to be exorbitant), or marketing reasons (operations by others have provided a glut, prices have dropped, and the proposed operation will not be competitive).

It is easier to stay with an existing well-known activity, but if projected growth, R&D, or competitive analysis along with other factors indicate a bright outlook for the gold business, a medium attractiveness for copper, and a dismal future for nickel, all things being equal, the company should consider directing its new investment to the favorable sector. This decision, however, should be scrutinized and challenged by asking if the new strategy is consistent with the existing and future business environments, the company's resources, and its management experience and capabilities. And, it should be determined whether the company is truly prepared to accept the risks of pursuing a new strategy and seeing it through. This analysis requires thoughtful answers to a myriad of questions, of which the following are only a small sampling:

Is the strategy likely to initiate antitrust opposition?

Does the strategy bring the enterprise in direct competition with a powerful adversary?

Does the strategy utilize the company's strengths and avoid its weaknesses?

Does the company have managers to implement the strategy?

Is sufficient capital available or can it be obtained to see the strategy through, even if a recession develops at a critical point during the development period?

Does the strategy take the company too far from its current market and expertise?

Are the basic decision data and assumptions reasonably accurate and realistic?

A penetrating investigation and analysis requires time and objectivity, but can be a valuable aid in selecting or rejecting a particular strategy. If the strategy stands up under scrutiny, often the investigative effort provides information that will be helpful in implementing the new strategy. Also, study of the competition may turn up candidates for acquisition or joint venturing, properties that are in need of exploration funding, or areas that justify grassroots exploration.

Diversification is often selected as a strategy of the growth-oriented firm, and a noted business planning author, George Steiner, states that the managerial imperatives are "... diversify or die, and diversify by plan." Some might take exception to this statement, but the low prices and reduction in demand that often accompany business cycles encourage the mining company to search for countercyclical earnings. Diversification means a movement into new markets, product lines, processes, or services. The justifications for such moves are varied, and in addition to stability include a desire for growth, a broader product line, and an opportunity to reduce costs. As noted earlier, growth can come from internal efforts or from acquisition. Peter Grace, CEO of W. R. Grace, is an advocate of the latter. He comments: "My basic philosophy is that you have to be big to take risks and you have to take risks to grow. If there's one way to get big without buying companies, I haven't found it yet." On the other hand, H. Barclay Morley, CEO of Stauffer

Chemical, takes the opposite view, espousing a strategy of internal development. Both companies have been exceptionally successful, and both methods of growth should be considered, but the successful strategy will depend on the philosophy of top management and the particular strengths within the enterprise. Peter Grace has done a fine job of restructuring his company and managing growth by acquisition, but many others have been less fortunate.

Volumes have been written on acquisitions, mergers, and diversification, and while indepth coverage cannot be given here, several key points should be made. First, statistics and analysis do not support the thesis that mergers and acquisitions improve corporate performance and shareholder investment. And secondly, analysis does indicate that diversification and growth are most effective if made in related fields and businesses. Furthermore, studies have shown that most acquisitions, especially acquisitions of huge companies, do not work out. Obviously participants do not proudly advertise their failures, but some experts say that seven out of ten acquisitions fall short of their initial objectives. A noted specialist in corporate mergers states that "... of the 50,000 mergers undertaken over the past 30 years, over half of the companies acquired by larger companies have been weakened, damaged, or totally destroyed." This is a strong indictment of mergers, and the acquisition-minded strategist should be aware of the record and the odds faced in pursuing such growth.

Similar studies show that firms that diversify by developing or acquiring units related to their existing activities are more profitable than those that pursue strategies of unrelated diversification. Further analysis indicates that the most important dimension of relatedness is that of management competence and attitude. This idea is also supported by a comprehensive study done by UCLA's Richard Rumelt who found that "... related-constrained (controlled) diversification strategies unquestionably gave the best performance." Rumelt also states that "... these companies have strategies of entering only those businesses that build on, draw strength from, and enlarge some central strength or competence." While such firms frequently develop new products and enter new businesses, they are loath to invest in areas that are unfamiliar to management. The central point of Rumelt's study is that companies that branch out somewhat, yet still stay close to their primary skill, outperform all others. Few mining companies have been successful in diversification well outside mining, and even fewer can show excellent results.

An obvious reason for staying close to familiar fields is to use existing capability. If the goal of the enterprise is to be the premium producer and marketer of gold in the US and its strategic plan gives no consideration to personnel having the capabilities to accomplish these tasks, it may be wishful thinking to assume the existing staff is competent and able to perform the required tasks. The firm that succeeds is the one that is willing to develop the clear, superior capabilities that are decisive to success. Skills can be learned, and if the need exists, the wise company will attempt to gain the required experience before entering the business.

IMPLEMENTATION

Strategy implementation requires decisions about organization, communication methods, control procedures, and performance measurements. Achievement of these tasks requires practices and attitudes for performing most major functions. Of paramount importance is a keen interest on

the part of top management and a planned program of implementation.

Organization

Responsibility for implementing the strategy must be assigned, and the timing, methods, financial needs, and potential markets determined. Proper coordination will require the attention of those directly and indirectly involved, but also the support and monitoring of top management. It is also likely that some form of new organizational structure will be required. If so, there should be a willingness to alter the structure since the existing organization may hinder new efforts and act as a roadblock to progress. Alfred Chandler, the noted business historian, coined the phrase, "Structure follows strategy," in his 1962 landmark study, *Strategy and Structure*, and this concept is still embraced by management specialists. It means simply that the organizational structure should be tailored to the strategy to be pursued.

An alteration in strategy can indeed lead to a realignment of the organizational structure as some activities may be expanded while others are curtailed. If the new strategy and organization are not in tune, it is likely that the desired objective will not be achieved. Ideally, the staff and management that formulate the plan would also be involved in its implementation. It is understandable that those who helped shape the program will more readily appreciate and accept its objectives and strategy, and in addition should be more qualified to successfully shepherd it to fruition. Also, most organizations prefer to assign implementation of the new tasks to existing managers, especially if the new activity is related to an ongoing business. Lastly, the structure of the organization should be as simple or complex as required, but the simpler the structure, the better.

Communication

As noted above, utilizing the planning team in the implementation phase is invaluable, and nowhere is this more apparent than in communicating and disseminating the program. Proper action can only follow if all involved understand the purpose of proposed strategies, and few are more knowledgeable about this than the draftsmen. The chief communicator should be the firm's CEO since his opinions are highly valued and his enthusiastic support illustrates a strong commitment to the organization. His best communication device is the written plan itself. If properly stated and distributed, it will give the basic strategy, proposed action, and methods for attaining the desired objectives. Whether special written instructions should be utilized depends on the number of individuals involved in implementation, the amount of time that will pass before the work is completed, the degree of complexity or detailed information involved, and if the matter is of such importance that special written steps are warranted to eliminate misunderstandings.

Controls and Performance Measurement

The primary objective of controls is to steer action toward the desired goals. The process starts with the manager agreeing with his superior about the results that he is expected to achieve within a certain period of time. This agreement should be based on an understanding about the organization, the desired goals, how performance will be measured, and the freedom and restrictions of the manager. At the end of the period, performance is appraised, shortcomings and better-than-expected results are discussed, and objectives for the future are established. Motivation to perform is based on a variety of rewards, including financial gains, recognition, social status, promotional opportunities, and a personal sense

of achievement. The key to any incentive program is establishing a belief that appraisals will be undertaken and that they will be objective, with rewards given fairly.

PROBLEMS AND CAVEATS OF PLANNING

While many think that strategic planning, if performed *properly*, assures success, the cold light of reality often shows this not to be the case. Some of the original assumptions may be invalid, underestimated, or just plain wrong, and if so, and a continuation of the strategy strongly indicates the likelihood of failure, a prompt change of direction or a complete halt to implementation is justified. Any plan or program should be flexible, as it would be foolhardy to follow a strategy when new facts or better knowledge show some key assumptions to be wrong.

Similarly, if the programs that formed the basis for the strategy change, modifications should be initiated. As an example, if funding for entry into a new business is dependent upon cash flow from ongoing operations and a severe recession develops, prudence would call for an alteration of plans. Additionally, if trends and events turn out dramatically different from estimate, the company should be prepared to act accordingly. Frequently projections and assumptions are wrong. Competent planners and managers will attempt to foresee pitfalls and fix the limits and deviations that may be tolerated from the original plan, and they should be prepared to respond (stop, go slow, sell off) if the actual situation deviates markedly from the forecast. Well-thought-out sensitivity, *worst case* and *what if* (negatively inclined), analyses enable the enterprise to act in a rational, panic-free manner if assumptions prove inaccurate. Fear, uncertainty, and over-concern for disaster can cause indecision and inaction, but failure to challenge new corporate directions can be devastating.

Obviously the sooner an error-based strategy is detected, the less problems and damage it will cause. In many instances this does not mean abandonment of the original strategy, but it may call for significant modification of plans or a deferral of action. As an example, if construction of a major new silver operation for a well-established copper company is based on revenue from its copper business, consideration should be given to selling forward a portion of the projected copper production or arranging financing, even though it may appear that borrowing is unnecessary. Likewise, loan commitment fees that give security and provide funds for completion of a project may be a small price to pay for allowing construction to proceed on plan. Similarly, contingency plans can be developed for cost overruns, changes in markets, technical errors, and other critical assumptions, and such plans are best considered in the early stages of planning rather than when disaster strikes.

There are innumerable pitfalls in developing and executing the strategic plan, and recognition of these can circumvent problems and reduce frustrating and time-consuming deliberation. Improper management of the planning function itself can ring the death knell. Slow implementation decisions, too much reliance on committees, too many planners, poor communication of plans, and lack of support at the top are commonly listed as reasons for failure. Chief among these is disinterest or lack of CEO support. Commitment of the CEO is required of many management programs and functions, but it is critical to strategic planning because this activity is often viewed as superfluous. While it can be complex and confusing to the uninitiated, and is time-consuming, it should not be perceived as interfering with placing rock in the box. The firm hand of the top man is

required, but more important is the fact that the strategic plan should reflect the thinking and goals of the CEO. It is impossible for his desires and judgments to be incorporated without his direct involvement.

Planning Is No Substitute for Management

Strategic planning is no substitute for good management. If management fails to mind the store, the store may go broke while the sophisticated plan is being assembled. Maintaining production, low costs, high productivity, a good balance sheet, and control of the enterprise are still necessary functions and will remain the key responsibilities of management. Several years ago the planning of a particular international natural resource company was held up as the model for our industry. It had large market research, forecasting, and strategic planning groups, and its bold acquisition and expansion activities were supposed to give a diversity that could withstand the cycles of our industry. Time has passed, and in the 1981-84 recession, the company had more than its share of difficulties, and it is doubtful that it will ever recover to its prerecession strength and lofty industry position. A number of other resource companies had similar experiences, and this was attributed to a disregard for basic business principles (poor marketing, elevated debt level, high costs, and excessive overhead) and a belief that higher prices would persist indefinitely. These comments are not an indictment of strategic planning, but again prove that proper management is a multifaceted activity requiring constant attention.

In the ever-changing field of management science, and with the challenges created by the severe swings of the business cycle, few planning concepts withstand criticism indefinitely. Currently it is questioned whether strategic planning is the primary force that moves a corporation forward, or whether planning and its required structure are just two of several key factors. Many management consultants are now marketing an ability to assist business in developing skills and programs for *all* the critical factors. The McKinsey 7-S Framework (Fig. 6) has been a highly touted concept within the last year or two. The 7-S approach calls for the *Strategy* and *Structure* of Strategic Planning, but these must be accompanied by *Staff* (the people of the enterprise), *Skills* (the company's know-how), *Style* (manner in which management

Fig. 6. McKinsey 7-S framework.

and employees conduct themselves), *Systems* (enterprise's methods of communication), and *Shared Values* (the so-called culture of the organization). These 7-Ss are further explained by Waterman of McKinsey and Co.:

Strategy—A coherent set of actions aimed at gaining a sustainable advantage over competition, improving position vis-a-vis customers, or allocating resources.

Structure—The organization chart and accompanying baggage that show who reports to whom and how tasks are both divided up and integrated.

Staff—The people in an organization. Here it is very useful to think not about individual personalities but about corporate demographics.

Style—Tangible evidence of what management considers important by the way it collectively spends time and attention and uses symbolic behavior. It is not what management says that is important, but the way management behaves.

Systems—The processes and flows that show how an organization gets things done from day to day (information systems, capital budgeting systems, manufacturing processes, quality control systems, and performance measurement systems all would be good examples).

Shared Values—(or superordinate goals). The values that go beyond, but might well include, simple goal statements in determining corporate destiny. To fit the concept, these values must be shared by most people in an organization.

Skills—A derivative of the rest. Skills are those capabilities that are possessed by an organization as a whole as opposed to the people in it. The concept of corporate skill as something different from the summation of the people in it seems difficult for many to grasp; however, some organizations that hire only the best and the brightest cannot get seemingly simple things done while others perform extraordinary feats with ordinary people.

Proponents of this concept claim that success is based on the proper interaction of the factors with one another and with the corporate environment, and for strategy to work, all the factors must fit. They must each support the strategy, and if not, changes must be made to accommodate the anomalous variables, or the strategy should be modified or abandoned.

Over the years other multivariable concepts have been proffered, including the *Management Diamond* (task, structure, people, information and control, and environment) by Harold Leavitt, and *Six Factors* (same as 7-S less *Skills*) by Harvard's Anthony Athos and Richard Pascale. It is apparent that there are many opinions on the necessary components of good management, and most would agree that strategic planning is just one of them.

Responsibility for Strategic Planning

All key elements (internal and external) of the business must be considered in formulating a strategic plan, and this requires inputs and analysis from practically every manager of the firm. Likewise, the development and execution of strategies involves the contribution, support, and action of operating managers as well as staff personnel. Normally the greater the degree of participation, the more effective the plan. Therefore, there are benefits in assigning certain planning responsibilities to practically all managers. Clearly the CEO is the prime mover, and his participation and commitment must be conveyed to all concerned. He should have the broadest perspective of the firm's business today and its potential tomorrow, and therefore he must be viewed as the chief planner. Granted, assistance can be drawn from the entire organization, and a small planning staff may be jus-

tified, but the CEO must make the key planning decisions. Many companies have no separately responsible staff for planning; others have only one or two individuals; and as would be expected, some have large, well-supported departments. Usually the size and complexity of planning staffs depend on the size and complexity of the organization, the style and preferences of top management, and the existing organizational structure of the firm.

Others are also involved in planning. The CEO is the key architect, but his decisions should be critiqued by the board of directors. This group has the responsibility for seeing that the company has an effective strategy, and obviously this requires that they understand what constitutes an effective strategy and know the strategy is pursued. The CEO should keep the board informed by at least reporting the highlights of the planning process, and in some companies, all major policy and strategy decisions are discussed by the board prior to taking action. The latter approach allows better feedback and is more likely to give management the benefit of the board's thinking and judgment. In summary, many are involved and have responsibilities for strategic planning, managers, senior officers, the CEO, and the board of directors, and all can contribute, but the CEO is the linchpin.

Now that the justification for strategic planning has been considered, its formal procedures scanned, and some of its shortcomings noted, the question to ask is: Is it really worth the effort? This author believes the answer is a resounding, but qualified, *Yes*. The qualifications relate primarily to the company's existing level and degree of planning and to the procedures that should be followed.

If in the past the company has done little strategic planning, it should move forward with deliberation. Action should generally follow the flowsheet in Fig. 7, but in small steps. After gaining experience and confidence in the method, more intricate and comprehensive planning can be considered. One should resist the temptation to launch a full-scale campaign until the knowledge and acceptance level of the organization have evolved to the point where these new ideas can be assimilated.

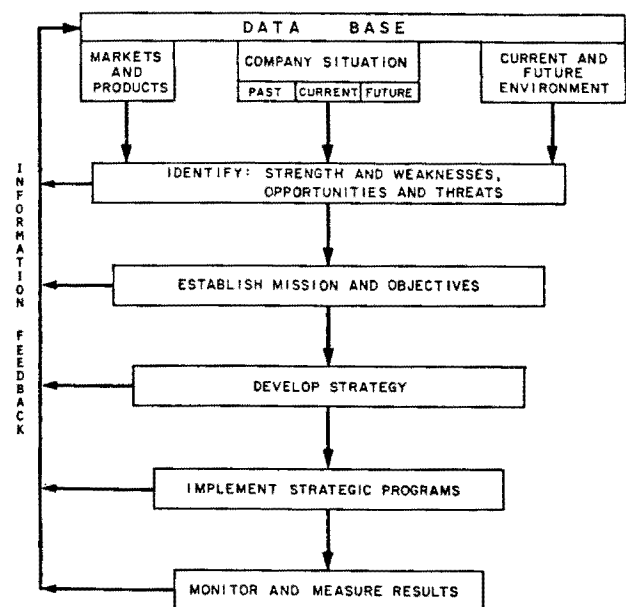

Fig. 7. Strategic planning—action flow.

Planning can be initiated in a gathering of the top corps of management during which the merits and need for strategic planning are discussed, questions are asked and answered about what the firm should look like five years in the future, and preliminary decisions are reached about how to guide the enterprise along a path for fulfilling this new ambition. To be sure, all these decisions cannot be made in one session, but the preliminary discussion can be used to obtain the commitment of senior management and set the stage for future planning. The steps of Fig. 7 are recommended, but they should be tempered as follows:

Strengths and Weaknesses—The study of the company's strengths, weaknesses, markets, and competition is invaluable. This analysis points out the threats and opportunities of the enterprise, and serves as the basis for all other planning—therefore it should be done well, incorporating inputs and ideas from all levels of the organization.

Missions and Objectives—The business of the company (its mission) and goals (objectives) that it must pursue to fulfill its mission should be understood by all employees. The initial list of objectives should be limited and relate only to those key activities that may make or break the business. The list can include minimum financial objectives (targets of sales, net income, return on investment), objectives that will maintain competitiveness of the company (productivity, cost control, methods improvement, diverse markets), and objectives that focus on the people and spirit of the organization. In the beginning, objectives should not be overly ambitious. Give the system a chance to evolve and be accepted.

Strategy Development—Keep it simple. Use the ideas indicated by the appraisal, new concepts of top management, quality approaches suggested by R&D, and worthwhile practices of the competition. Do not be reluctant to wait for the opportunities that will come to the competent, well-managed company. Go slow in relying on the complex fashionable techniques of strategy development. Portfolio theory, product-market matrices, and other fashionable, sophisticated methods may have value, but they can be time-consuming, frustrating, and difficult to apply to the minerals industry. A strategy that leads to dramatic restructuring, challenging acquisitions, and new, *exciting growth* business has appeal, but it may be fraught with risk. Many companies have initiated change, redeployed assets and established a new base just in time to find that others also thought this was an *exciting growth* business. Inevitably, oversupply, low prices, and tough competition will follow. The most profitable strategy will probably be that which focuses on improved marketing practices, productivity increases, cost reduction, incremental expansion, recovering byproducts, and other opportunities related to the existing business. While this is not as glamorous as other approaches, it can lead to solid growth.

Strategy Implementation and Monitoring—Do not assume that strategy must be changed every year or on any particular schedule. It ought to be reviewed and critiqued annually, but if properly conceived, it should serve the company well for years, if not decades. If at all possible, the task of implementing new strategies should be assigned to existing management and made a part of the ongoing business. Action should be monitored, controlled, and appraised by existing methods and organizational structure, and those responsible should be aware that their personal advancement and rewards will be influenced by the manner in which the strategic plan is implemented and administered.

Diversification—A diversity of products or businesses has value, particularly if the products follow a countercyclical pricing trend; that is, if the bottom of the copper market

does not occur at the same time as a slump in phosphoric acid (fertilizer) sales. Recognize that diversification can be accomplished without going too far afield. The impact of metal cycles may be mitigated to a large extent by developing or producing a variety of metals, certain industrial minerals, specialty chemicals, or energy fuels. In a deep, severe world recession, however, few if any businesses will be fully immune from decreased demand and low prices.

The value of broad scale diversification can and has been challenged. Statistics support the conclusion that nondiversified companies, on average, achieve faster growth and superior returns on investment. This is the reason that restructuring, a return to the core business, and divestment of unrelated activities are now in vogue. Relatedly, the manager that can create efficiency, reduce costs, and increase output is now in demand. How so? Why and where did the broad gage strategist and portfolio manager go? Well, times change, philosophy and management practices shift, and the needs of the enterprise are different. The sensitive manager responds. The natural resource company must seek growth, especially since its resources (ore bodies) are depleting, but many would say this should only be in related areas—areas in which management has most of the skills and knowledge required for success. If a move to a completely different business, such as consumer goods or service sectors, seems justified because of unusual circumstances or an exceptional opportunity, this can best be accomplished with partners that bring experience and knowledge to the venture.

In placing strategic planning in perspective, one should keep in mind the primary responsibilities of management—to assure survival and profitable growth of the enterprise—and realize that this is accomplished by performing a few tasks and performing them well. The 7-S, 6-S, or X-S key functions of management discussed earlier are worthwhile and should be understood and possibly applied, but none should overwhelm the others. Strategy development is an important and necessary activity, but the key strategy should be to first manage the fundamentals of the business, then seek the new.

Productivity and performance studies have shown that the average business fails to realize half its potential, and if this is the case, the guiding principle of Theodore Roosevelt, "... to do what you can, with what you have, where you are," should be the first step in strategic planning.

8.4 Human Resource Management

ANNETTE DUPREE

INTRODUCTION

A company has available many resources to ensure success and profitability. Among these, the human resource is a most valuable one. After all, what is an organization made up of but people at work.

The administration, maintenance, and management of people in a company is called *human resource management*. In the last decade, human resource management has evolved from a narrow concern to a general management awareness of the important role employees play in the success of a company.

Earlier human resource administration concentrated on maintenance aspects like hiring, firing, and paperwork. Today's human resource responsibility is much broader and is a basic management responsibility, from the President or Chief Executive Officer on down. Personnel administration permeates all levels and types of managers and every manager needs to be an effective human resource administrator.

The personnel specialists in a company aids managers in getting more effective results from their people. Specialists provide advice, counsel, and procedures for consistent administration of personnel policies. The human resource specialists play a strategic role, linking their activities with the overall business objectives of the company.

Human resource management is not simply a matter of developing and applying policies and procedures, but a matter of working with people who have unique feelings and thoughts. It is concerned with the worker as an individual, worker satisfaction, communication, motivation, and productivity.

The decade of the eighties brings many new challenges to the field of Human Resource Management in the mining industry. Technology will continue to expand as it has since the late fifties but at a quicker pace. Just as capital expansions, the emergence of mining and mineral conglomerates and labor confrontations dominated the first half of this century, the future of mining Human Resource Management will center around the development of employees, the elimination of meaningless work and the mutual success of the employee and the organization working together for their mutual benefit (Scobel, 1982).

Human resource management has several functions:

- Recruiting and selection.
- Compensation.
- Training and development.
- Performance measurement.
- Communication.
- Union-management relations.

These functions are all interrelated and they do not work independently of each other.

RECRUITING AND SELECTION

Having a sound selection system is one way to insure a solid foundation of human resources. The success of a company, in many ways, is dependent upon its ability to recruit, select, place, and retain qualified people.

Recruiting is anything done to fill a vacancy. Recruiting

may be directed internally by use of inter or intradepartmental promotion or transfer, or externally where people are sought from outside the company.

To a great extent, the success achieved in hiring competent people is a direct result of recruiting. A large enough pool of applicants must be attracted so no compromise is made on the selection standards.

What method is chosen to recruit depends on the nature of the job, the immediacy of need, and the cost. Sources available for recruiting include college placement offices, trade or business associations, newspaper advertisements, employee referrals, public employment services, private employment agencies, and advertisements in trade journals. Effective recruiting should be done on a continual basis, not only when a job opening occurs.

The objective of the employment interview is to gather enough information about the applicant concerning skills and interests to make a hiring decision. Very simply, the objective of the employment interview is to match the applicant to the job.

Employment interviewing can be more successful by planning and preparing for the interview. Most interviews are started with little preparation. The steps in preparation are:

1. Determining the job content.
2. Developing questions.
3. Examining the application blank.

Determining the content involves breaking down the job into the duties, skills, experience, and education needed to perform the job. It is most important that the requirements be specifically related to the job and are minimum qualifications. The job content can come from a prepared job description, the manager, or a person who has performed the job.

The primary purpose of questioning is to get information from the applicant as a basis for making a sound hiring decision. Effective questioning stimulates the applicant to think and motivates him to discuss. Of the two types of questions, directive and nondirective, the latter is usually most appropriate. Nondirective, or open, questions are ones that do not lead the applicant to a yes or no answer. Open questions, like "How do you feel about your last job?" encourage applicants to think and share their ideas and observations. Directive questions are best when a specific answer is needed. Otherwise, directive questions lead the applicant to the desired answer.

The application form contains a lot of information and should be reviewed carefully. It gives the interviewer information about the skill and experience level of the applicant. Be thorough in reviewing the application, considering the way in which the form was filled out. Is it neatly done? Is it complete, signed, and dated?

Choose a private place to interview the applicant, one where there will be no interruptions or phone calls. At first, spend a few minutes talking to help the applicant feel at ease. Outline the interview to let the applicant know in advance what is going to happen during the interview. The more the interviewer can create a pleasant environment and put the applicant at ease, the more productive and effective the interview will be.

During the interview obtain information from the applicant relating to training, work experience, job progress, earning progress, relationships with supervisors, and reasons for leaving previous jobs. Also, the interviewer should give information concerning the specifics of the job, the company, the benefits, and other things the applicant needs to know.

After the information is obtained, it must be analyzed and evaluated. A proper match of the individual to the job must be made. It is important to take the guesswork, or gut feelings, out of the decision-making process and base hiring decisions on job related factors. The interviewer must have a clear understanding of the job, what he or she is looking for and if it was found in the interview.

COMPENSATION

The basis of the employee-employer relationship is that employees are hired to do work for which they are compensated by the employer.

Compensation addresses two issues. One is direct compensation, such as wages and salaries. The other is indirect compensation or benefits. Establishing compensation objectives and developing plans and programs that will help achieve these objectives is very important.

Objectives, once developed, should be communicated to all employees. Each employee at a mine, for example, should understand that levels of pay are determined by job skills and responsibilities, what other mines are paying for comparable jobs, how well the employee performs his job, and how long the employee has been in the job.

Generally accepted principles for effective wage and salary administration have been identified through the years as relating to one or more of the following:

1. A fair day's pay for a fair day's work.
2. Attract, retain, and motivate high performing people.
3. Encourage and increase productivity.
4. Maintain internal and external equity among jobs within the company and realistically compare jobs to similar ones outside the company.
5. Budget and control.
6. Lessen complaints and antagonisms.

For the employer, the cost of compensating employees is not limited to wages and salaries. A large percentage of payroll costs is in the form of indirect compensation or benefits.

Indirect compensation should provide employees with a choice of benefits that meet their needs and wants. Benefits can be group medical, life, accident, and dental insurance or in the form of paid time off such as holidays, vacations, and leaves of absence. Capital accumulation programs in the form of savings and investment plans, profit sharing, and employee stock ownership plans are becoming more important as the employee sees the value of the dollar declining through inflation, the instability of the Social Security System, and the high cost of education, housing, etc.

TRAINING AND DEVELOPMENT

Whether or not a company has a formal training program, training is going on all the time. Employees, through time, pick up skills, habits, and attitudes of others in the workplace.

Training is an investment in a person so he can make greater contributions to the company's future. Training can be on-the-job, classroom instruction, apprenticeships, or self-designed programs.

An effective training program can:

1. Improve employee performance, quality, and quantity.

2. Prepare the employee to meet new challenges in technology, product, or environment.
3. Promote and transfer employees.
4. Improve employee morale, reduce absenteeism and turnover.
5. Lead to fewer on-the-job accidents.

Training needs should first be assessed. Who will benefit? What type of training is needed? A system should also be set up to evaluate the effectiveness of the training. Training charts can be helpful in assessing and meeting training needs. See Fig. 1.

All new employees, regardless of experience and education, need to be introduced to the new work environment and taught the specifics of the new job. The initial induction, or orientation, is where training and development begins.

It is important that employees start off in the right direction, feel welcome, and know the policies under which they will be working. Orientation should include an introduction to the company (history and future plans), the compensation package, the company product or service, how the employee fits into the overall picture, and the basic work rules and policies. See Fig. 2, Checklist for Employee Orientation, for an outline of topics to be covered. In many ways the success of the new employee depends on the amount of time spent and the amount of information covered in the orientation process.

PERFORMANCE MEASUREMENT

Increasing productivity is a concern of many companies today. Saying a "200% increase in productivity is needed" has little meaning to an employee. It must be translated into the specific contribution the employee can and should make.

Of the variety of plans and approaches available to increase productivity, one thread that seems to run through all of the approaches is meaningful and timely feedback on employee performance. Performance measurement and evaluation is a tool to better communicate work expectations.

Objective performance standards are the key to a successful performance appraisal program. A performance standard is the performance condition that will exist when a job is being done according to the expectation of the company and the employee. Performance standards are written from job-related criteria that are measurable, attainable, and observable.

Measurability refers to how well the job is being done, i.e., loads per day, how fast loaded. Measurability of standards looks at quality, quantity, time and possibly, cost factors.

Of course, standards should be written so the employee can attain them. Performance standards should be practical and realistic.

Observability is the ability to actually see the standard of performance being met. Can the manager and employee see the levels of measurability being met? Can the manager and the employee see progress or lack of progress in job performance?

Without standards, a performance system might be based on personality traits, like attitude, initiative, or cooperation. This results in judging the employee as a person. The method of measurement is unclear and is based on the subjectivity or opinion of the rater. Systems without well communicated and defined standards of performance can promote defensiveness in the employee being evaluated and result in disagreements in performance rating. The employee does not know what is expected and may find out when it is too late.

Performance appraisal is not an every-six-month or once-

[illegible]

Fig. 1. Training Chart

a-year occurrence. It is daily feedback and daily activity for the manager and the employee.

A formal performance interview is putting in writing what has been collected throughout the performance period. There should be no surprises in store for the employee.

Performance measurement or management systems must also look at mutual goal setting and development to be successful and effective. Employees have a stronger commitment to goals if they participate in the development.

COMMUNICATION

A communication program is a vital part of the human resource effort. Communication systems can greatly assist work flow and create a climate of understanding in a company. In fact, communication is such an essential part that any discussion of human resource management deals with communication.

Recruiting and selection, matching the applicant to the job, is done through communication. Interviewing is a conversation with the purpose of making a selection decision.

Acceptance by employees of a wage and salary plan is achieved through communication. The more the employee knows about the way a company pays, the greater the acceptance.

Training and performance appraisal is daily communication and interaction between management and employees.

The effectiveness of a company's policies and procedures will depend on the communication system. An employee handbook is an excellent device to communicate to the employee and his family, the benefits and policies of the company. A formal policies and procedures manual helps managers communicate and apply company policies and work rules in a fair and consistent manner. The communication process is especially important when new practices are introduced or changes are made in existing policies.

Other communication devices are suggestion systems, bulletin boards, and opinion surveys.

Communication is a two-way design, keeping employees informed and giving them an opportunity to express their ideas, questions, complaints, and concerns to management.

Fig. 2. Checklist for Employee Orientation

A necessary part of the communication effort is letting people know where their jobs fit in the company. The orderly arrangement of jobs and duties is of little value to employees unless they know what they are supposed to do and what their role is in meeting the overall company objectives.

Organizational structure is concerned with (1) role and task definition, (2) organization charts, and (3) communication and information flow.

Organization charts show the role and task definition and provide the grouping of activities into a logical structure. It provides the identification and relationships of functions of the company and is a graphic picture of the lines of authority of the company, showing by job title who reports to whom. Organization charts also help provide answers to questions such as:

1. Who am I; what is my position in the company?
2. What do I do?
3. To whom am I accountable?
4. Who is accountable to me?

UNION-MANAGEMENT RELATIONS

Ineffective human resource administration can possibly bring a new role to management, union-employee relations. If a company has arbitrary policies and procedures, wages and benefits that are not consistent and competitive, and has poor lines of communication, union intervention is likely.

Even with bargaining expanding to areas of benefits, work hours, and work rules, union organizers use the issues of wages and working conditions as big selling points. The employer who is perceived by the employees as not competitive in the area of wages or unfair in the treatment of employees could be in a position that looks attractive to union organizers.

Organizing can also be instigated by employees within the company. The National Labor Relations Act, a federal law, refers to such acts as "protected concerted activity," which is described as two or more employees or one, if the employee speaks for several others, who protest a working condition or who attempt to seek union representation.

No matter if the organizing attempt comes from an outside union organizer or the disgruntled employee, the employer has to acknowledge the activities and their protection under the law.

One of a union's first steps in an organizing drive is to obtain authorization cards from employees. See Fig. 3. When this occurs, there are various responses management may make. The following guidelines will assist management in answering questions that frequently arise. First, however, some general precautions:

1. Do NOT examine any documents or cards a union representative offers to show management.
2. Do NOT discuss any contract proposals or company policies with a union representative.
3. If management receives a letter from the union asserting that it represents a majority of employees, respond with these words and NOTHING ELSE: "I have a good faith doubt your labor organization does in fact represent an uncoerced majority of my employees in an appropriate bargaining unit, and I suggest you may wish to avail yourself of the orderly procedures available at the National Labor Relations Board to resolve any question of representation."
4. Bear in mind that the rules regarding campaign conduct are extremely complex and that union organizers are trained professionals. Lacking competent advice, an employer can very easily become entangled with the National Labor Relations Board.

CONCLUSIONS

People are the core element in any company. The management of people, human resources management, will no doubt play a bigger role in the future. With changes in the workforce, and pressures from technology and the economy, greater emphasis must be placed on the management of this most valuable resource.

RESPONSIBILITY COST ACCOUNTING AND BUDGETING

Introduction

The objective of responsibility accounting is to provide reports of the costs for which each manager is responsible. It provides a method for budget development, and timely comparisons of actual expenditures with budgets. This encourages each manager to deal frequently with budgets and costs. Managers act to correct unfavorable trends in costs versus budgets. They realize the effect of action taken, and the importance of maintaining control over costs.

It is important that managers understand the overall cost picture of the larger group, whether this is the department or the company. The costs associated with the manager's responsibility must be carefully delineated. A manager's responsibility report should include only those costs over which he has direct control. For example, managers should not receive information in their cost reports about equipment depreciation if they have no control over the purchase of new equipment. Nor should they be responsible for costs distributed from overhead or administrative cost centers.

It is not the objective of responsibility accounting to present an accurate product cost or financial picture to the responsible manager. The objective is to make him aware of the effect of his actions on the costs in his responsibility area.

This section describes the principles and operation of a responsibility accounting system. It discusses the breakdown of departments into cost centers, and the generation of budgets for them. It also discusses responsibility reports comparing budgets to expenditures. Finally, it includes a description of a budget and cost control cycle.

Cost Centers and Cost Elements

Cost Centers are the smallest division into responsibility areas. Examples of typical cost centers within a mining department are administration, production drilling, production blasting, and hauling. A manager is responsible for the costs within each cost center.

Cost centers contain *cost elements*, such as labor, drill bits, and cleaning supplies. Careful assignment of elements of costs to the cost centers is important. It is typical in a mining department to have separate cost centers for haul truck maintenance and for material hauling. A clear definition of which materials and supplies apply to which of these cost centers is important. Wear steel is typically assigned to the operations cost centers. Mechanical spares are typically assigned to the maintenance cost centers.

There are commonly three types of cost centers within an operation. The first is an operating cost center. Examples of operating cost centers are the production drilling, production blasting, and hauling cost centers mentioned previously.

Second are service cost centers. Examples of service cost centers are the maintenance cost centers, such as haul truck repair and electrical power distribution. The reporting system distributes costs from the service cost centers to the operating cost centers. These costs appear in the responsibility reports twice. First they appear in the service cost center as a direct

cost under the responsibility of the service cost center head. They also appear under the operating cost center as an indirect cost or distributed cost. The responsibility cost report for a department must show a credit for internally billed costs to avoid double accounting.

The third type of cost center is administrative. These costs are overhead. The system does not distribute them to operating or service cost centers.

There are two types of elements within cost centers: direct and indirect. Direct cost elements include labor. They may include a number of different types of labor such as managerial, clerical, and wage. Other direct elements include operating supplies, maintenance supplies, and services and utilities purchased from outside the company. Indirect cost elements distribute charges from within the company for shops and other services. These are the distributed costs. Fig. 1 is a typical cost center report for an operating cost center. Fig. 2 is a report for a maintenance cost center, and Fig. 3 is a report for an administrative cost center.

Budgets and Estimates

The components of an operating budget system are:

- Prices.
- Basic standards.
- Dollar standards.
- Determinants.
- Determinant quantities, budgeted and actual.

Prices for direct cost elements are the standard unit price of the item. This may be the price per pound of blasting agent, or per hour for labor. Both the actual price charged and the price used in the budget development should be a constant standard price. This is because the cost center head cannot affect the price of these items. The standard price is adjusted from time to time.

Prices for indirect cost elements are the standard charging rate for the service cost center. The system develops the rate by dividing the total dollar budget for the service cost center by the budgeted units sold.

Basic standards are performance goals. They are consumption or usage rates, such as kilograms of frother per ton of concentrate. Kilograms of frother is the basic standard. Tons of concentrate is the determinant.

Dollar standards are either developed or are stand-alone standards. If there is a basic standard associated with a cost element, the system develops a dollar standard. It is the product of the basic standard and the price. If there is no basic standard, an analyst enters the dollar standard. An example of the latter is a standard for miscellaneous consumables of \$500 per month. \$500 is the dollar standard. Month is the determinant.

Determinants are descriptions of factors. Dollar standards are dollars per unit of a determinant. Examples of determinants are months, tons of ore produced, or truck operating hours.

Determinant quantities are the number of associated months, tons or hours. Budgeted determinant quantities are estimates of the factors. Multiplying these by the dollar standards before the year yields an annual estimate of expendi-

* DENOTES UNFAVORABLE VARIANCE

Fig. 3. Administrative cost center responsibility report.

tures. Actual determinant quantities are used at the end of an accounting period. The system multiplies them by dollar standards to yield responsibility budgets.

For variable costs, most systems use production determinants, such as tons hauled. For fixed costs, most systems use time determinants, such as calendar month. Variable budgets are functions of actual production levels. If actual production is zero, the total operating budget for the variable cost elements is zero. Budgets increase in direct proportion to the production level. An examination of the budget calculation detail report in Fig. 4 will give a clearer picture of the relationship between the different components described.

The selection of determinates is critical to the development of a budgeting system. A typical determinate for hauling is per 100 ton of material hauled. The budget for diesel fuel and wear steel for haulage trucks is a function of this determinate. In other words, the cost center head earns a budget of so many gallons (liters) of diesel fuel per 100 tons hauled and so many pounds (kilograms) of wear steel per 100 tons hauled.

Charges for the trucks themselves are distributed from the maintenance cost center to the haulage cost center at a standard rate. The standard rate per truck hour reflects the total cost of maintaining the truck. In other words, it is the business of the hauling cost center to haul materials with trucks. To do this, the hauling cost center rents the trucks from the maintenance cost center. It adds wear steel, diesel fuel, and other operating supplies.

Truck operating hours generate a budget in the maintenance cost center. It is the business of the maintenance cost center to provide haul trucks to the haulage cost center. Therefore, for every hour of actual truck usage, the maintenance cost center earns a budget for maintenance labor and supplies.

Responsibility Reports

Responsibility reports compare actual expenditures with budgets for each supervisor and manager. There are two types of responsibility reports. The first is the same form as a cost center report, illustrated in Figs. 1, 2, and 3. Consolidation of cost centers to higher levels follows the same format. Three cost center heads may report to one superintendent. The superintendent receives a report that combines the information for those three cost center heads. Fig. 5 illustrates such a report. This is an upper level statement for mine operations. Note that the report includes the name of the superintendent of mine operations which personalizes it. The format is the same as for cost center reports, with costs segregated by cost elements.

Fig. 6 illustrates a second format for presentation of upper level responsibility reports. This report lists the constituent segments within the superintendent's responsibility. In this case, they are mine operations administration, drilling and blasting, and mine production. The reports show credit for charges from one cost center to another. Note that the net responsibility costs for the two reports is the same.

The highest level report in the system is for the top level mine manager or company manager. It is similar in form to those illustrated in Figs. 5 and 6. Fig. 7 is an illustration of the use of the responsibility reports.

The reporting system deals with the last part of the objective stated previously. The highest level report, which goes to the vice president and general manager, shows there is a problem in the current month. There is a large variance in operations. Step 2 shows that the mining department accounts for the majority of the variance. In step 3, examining the responsibility reports within mining shows that mine shop maintenance and maintenance planning area has a variance accounting for most of the problem. Step 4 is an examination of the responsibility reports for mine maintenance. This shows an even larger variance for mine mechanical maintenance, truck and tractor. Step 5 is an examination of the report for mine mechanical maintenance, truck and tractor. Note that the responsibility report illustrated under step 5 shows costs both by element and by section. The total dollars on both reports is the same. An examination of both reports shows that the problem area is in the production truck maintenance department and in the maintenance materials element. Step 6 is an examination of the cost center report for production truck maintenance. The problem is located in the maintenance materials, mechanical mobile equipment. Finally, in step 7, a detailed costs transaction listing shows the makeup of the actual charges. They are located in the maintenance material, mechanical mobile equipment element. This report shows the use of eight repaired engines and four magnet frames. Thus, the report provides information for all levels of management to locate the source of cost overruns. Managers can take corrective action.

The system illustrated provides each manager with the information necessary to control costs. The managers are accountable for the costs within their responsibility. However, no system can reduce costs. To do this, people must change their behavior. One method of providing for this is through a budget and cost control cycle.

Budget and Cost Control Cycle

The cost control cycle must provide for an effective analysis of costs as they occur. It must provide awareness of costs to the manager and awareness of the effect of their management decisions on costs. This awareness must be in a time frame that will allow effective changes or modifications in decisions affecting costs. In other words, it cannot all be after the fact. An examination of last month's costs is meaningless unless it has an impact on spending this month.

The first step in the cycle is to estimate the cost. This is the mid-month estimate. A cost analyst prepares it with input on the major segments or elements of cost from the operating managers. This exercise does not produce a detailed report. It produces a report by element grouping of the total costs for the operations. Its purpose is to make the operations managers at all levels aware of any unusual expenditures that are taking place during the current month. The managers take corrective action if problems develop.

The second step is a comparison of the mid-month estimate with actual costs. Analysts compare them immediately after the close of the month. The comparison must be timely and not in great detail. Its value diminishes if it is not timely. It is available the third working day after the close of the month. By one day later, analysts present it to top level management with explanations for major variances. The responsible managers provide the explanations.

Within the first week after the close of the month, the

system produces cost center reports and other responsibility statements. Cost center heads hold a series of meetings. They analyze major variances between budgets and actual costs. They then prepare explanations of the variances for the superintendents, general superintendents, and higher levels. Top management holds a final meeting by the middle of the following month. It is critical that the meetings do not degenerate into a series of alibi sessions. The objective is to analyze variances between actual expenditures and budgets. People must change behavior in order to reduce variances. Managers must also analyze favorable variances. They may show that planned maintenance is not taking place.

The monthly cycle develops a high level of cost awareness. Operating managers develop annual budgets with staff assistance from the cost analysts. It is not advisable to change the annual operating budget unless warranted by a change in operating conditions, such as addition or deletion of machinery. The variable budgeting system automatically provides for changes in the production and operating levels.

It is important to remember that the purpose of the system is to control spending. Reducing variances by increasing budgets can be contrary to this. It is even more critical to remember that to control spending requires behavior modification. Reduction of budgets does not control spending. It can, however, serve to delude management. It can cause them to ignore real spending problems until it is too late for effective control.

PRODUCTION REPORTING

Introduction

Production reporting serves the primary purpose of advising managers of production performance. Production reports may express performance in either a quantitative or a qualitative manner or a combination of the two.

Production reports provide each responsibility head with the necessary information to assess production performance. The production performance relates to equipment, to people, or to both.

The system tailors production reports to fit the needs of each manager. They should contain only the information required, and no more.

Types of Reports

There are several types of production reports. The first consists of those prepared by the operator on a daily basis. An example is the shift report prepared by the operator of a power shovel. The report includes such data as equipment ID number, date, shift, location, and number of loads by category of material loaded. It also includes time of operation related to each product, delay hours or nonproduction time, and the reasons for these. The system prepares similar reports for trucks, drills, front-end loaders, draglines, and other pieces of mobile or semi-mobile equipment.

There are similar reports for other equipment such as tractors, graders, or cranes that provide service or support functions.

Plant operators prepare reports that express productivity in crude ore in and product out. It is also common to report on repairs made or required.

All reports mentioned have ingredients in common. They include an accounting of time, a description of the work done, and a report of equipment condition. Reports relating to some equipment yield production data that is quantifiable. They are expressed in units of work or production per unit

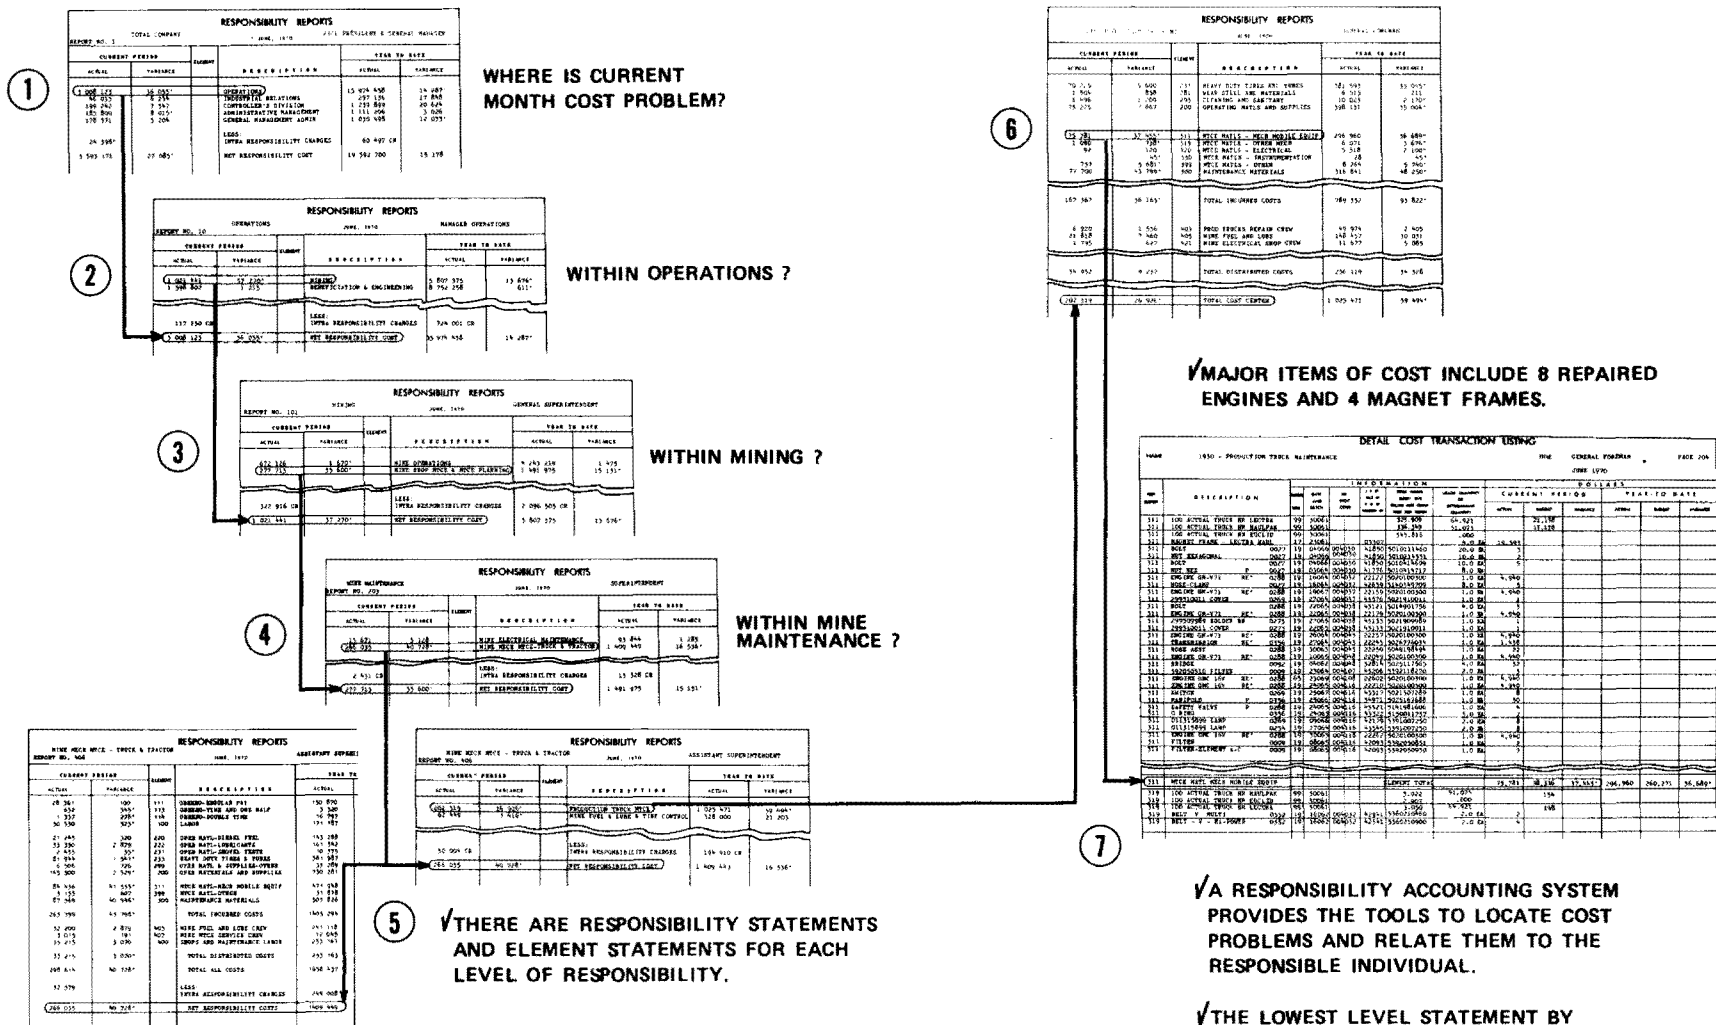

Fig. 7. Responsibility accounting cost statements. Source: Wraith III, W., 1973, "Section 30.8, Management Cost Control Systems—A Case Study," *SME Mining Engineering Handbook*, Vol. 2, I.A. Given, eds., AIME, New York pp. 30-64 and 30-65.

of time. The purpose of this type of production report is to provide raw data for input into more refined reports.

The second type of production reports are summaries. Data are compiled to provide production data on a time-related basis. In the summarization and compilation steps, it is common to convert the production units from a shift report to a more desirable unit of measure. Excavators and haulage trucks commonly report production in loads. In the summary process, it is common practice to apply a volume and/or a weight factor to convert loads to volume or weight. These units are more meaningful than loads in quantifying production. Similar steps relate meters (feet) of blast hole drilled to volume or weight. They may express explosive consumption in kilograms (pound) per unit of weight or unit of volume.

Reports of this second type show whether or not production goals are being met. Simple raw production quantities are readily available at all operations. They serve as one of the early indicators of operating performance. They are only an indicator, however, for in some cases high production levels are attained by sacrificing cost.

A third type of production report uses data from the two preceding report types. It expresses the productivity of equipment or of people. This information is one of the primary ingredients for repair or replacement evaluation. Time rate of production data is also valuable in comparing productivity of similar pieces of equipment of different makes.

Similarly, a comparison of the output of different people operating similar pieces of equipment serves as a basis for identifying substandard performers.

Production reports sometimes express productivity in quality rather than quantity. A common report sometimes incorporates quality and quantity data to present a composite basis for comparison.

Summary

The primary objective of every mining operation is economic mining and processing of a mineral. This should return a profit commensurate with the risk involved. A carefully conceived and carried-out system of production reporting is a valuable tool in the attainment of this objective.

The reporting system should yield timely and succinct information to the operator. The rapid advances in the field of electronic data processing promotes this process. Plant operations commonly use electronic means of controlling the operation. Computers produce reports that cover a wide range of information relative to production and general operating and maintenance data. Regardless of the methods of data collection and correlation, the reports are a valuable tool to the operator.

The effective operator is one who quickly reviews the information contained in the various forms of shift or monthly production reports. He makes maximum use of the data. The wise use of production report data results in greater productivity, improved quality, and lower product cost.

8.6 Sales and Marketing

STEVEN H. GRUNDSTEDT
JERALD S. MORRIS

WHAT IS MARKETING?

Frequently the marketing of mined products is narrowly depicted as the selling of run-of-mine ore to a custom mill, or the selling of concentrates to a smelter. These factors are certainly important, especially to metallic mines, however, marketing in mining is often a much broader field and can encompass a wide range of interrelated disciplines.

When marketing is discussed in mining, one should be cognizant of the variety of commodities produced from the world's mines. One convenient categorization of mine-run products breaks them down into four general areas: (1) minerals from which metals are extracted; (2) minerals used for their chemical and fertilizer properties; (3) minerals and materials used for their special or physical properties (e.g., gemstones and aggregates); and (4) minerals and materials used as sources of energy (Smith, 1982).

Since mining, and surface mining in particular, produces such a wide range of commodities, the marketing of these commodities is very diverse. Such marketing efforts will be simple or complex, dependent upon the commodities involved and upon trade requirements relative to grade and usable form (Parks, 1957).

Simply defined, marketing involves those activities that transfer goods and services from producer to consumer. Marketing is usually broken down into four main segments referred to as the *marketing mix*: (1) product, (2) distribution, (3) communications or promotion, and (4) price (Rewoldt, 1977). The marketing mix is applicable not only to commodities produced from surface mines, but also for all other products sold from any industry.

Product is that which is being offered for sale. This can be anything from run-of-mine metallic ore to different segregated sizes of limestone aggregate. It can be precious metal concentrates, ore, or refined bullion, depending on the final mine product. In the case of a completely vertically integrated copper company, the final product being offered for sale may be various grades and sizes of copper wire. In marketing, the term *product* may also refer to any of several different ancillary functions, such as the research and development of new (or modification of old) products; the decision to add or drop a product; and decisions to *brand* (national, private, or secondary) a product.

Distribution involves the movement of product from the place of production (mine, mill, refinery, manufacturing plant, packaging plant, etc.) to the place of sale. This not only includes modes of physical transportation but also the channels of product distribution as well; for example, direct sales, wholesalers vs. retailers, discounters, trade channels, etc.

Promotion is the actual selling of the product. Sales is often considered to be interchangeable with marketing, but, as has been shown, this is not correct (albeit sales is a very important component of marketing). Promotion, then, includes such things as personal selling, advertising, dealer incentives, budgeting, and media and message selection.

Price is involved with all of those actions and decisions concerning the dollar amount received for selling the product.

At what price level should the product be offered? Should the product ever be offered for less than this base price (e.g., volume discounts or geographic discounts)? Should a price schedule be changed, and why? These are all questions that are answered and subsequently implemented under the price segment of marketing.

The four segments of the marketing mix are not all mutually exclusive. Quite the contrary, they should be considered as interrelated, synergistic parts of the dynamic marketing process. A good example of the synergistic effect of the parts of the marketing mix is product service. Service is of major concern to the mine or production department since they have to produce a product that meets customer specifications; they are concerned with serving the customer a quality product. But service is also a major concern to the sales (promotion) people who directly interface with the customer. If a product is delivered and doesn't meet specifications, it is a problem that must be rectified by the production people; however, it is a problem as well for the sales people who must keep the customer satisfied through good service in order to generate future sales.

PLANNING, STRATEGY, AND RESEARCH

The first consideration of any marketing planning effort is to establish the marketing objectives. Actually, since marketing deals with the very basics of a business enterprise, the marketing objectives are dictated by, and must be consistent with, company objectives. Consequently, the marketing effort is limited by the financial resources of the firm. Thus, marketing objectives of expected sales volume and expected market position have to be able to achieve company forecasted gross margins and profit within company budgetary constraints.

During the planning stage, all major marketing policies must be formulated. These policies should comprehensively cover all major activities of the marketing department, including sales, price, distribution, advertising, and customer service as well as personnel policies. Formulation of policy, especially pricing policy, should take into consideration all regulatory guidelines. These guidelines can be obscure and complex and inadvertent violations of law must be carefully avoided.

The other important aspect having its inception in the planning stage is the assimilation of all of the facts, ideas, and support available from research and engineering, production personnel, finance, law, etc. (Rewoldt, 1977). The objective of this assimilation process could include any or all of the following: identification of existing or new markets; conceptualization and/or creation of new markets; the decision to enter (not enter) existing or new markets; the decision to expand (not to expand) present market position; maintenance of present market position. The assimilation process sets the stage for marketing strategy and any warranted subsequent action.

This assimilation process can be very simple, as would be the case of a small open-pit mine marketing its high-grade ore to a custom mill or smelter. This process could be quite extensive and complex as would be the case for a large

industrial minerals producer trying to establish a new, high-volume use for its product.

One of the severe constraints that all mining companies must contend with is that their mine's ore body is limited in both volume and quality. Hence, there is an ultimate limit on the amount (and on the specification) of product that can be delivered from a mine site. Practically, however, some mines have ore body lives that may exceed many decades (as is the case, for example, with some industrial minerals and coal producers, as well as a few foreign metalliferous producers).

When a mine has a limited life (i.e., the ore body will be exhausted in the short- to medium-term), the primary constraint on marketing efforts is generally the productive capacity of the mine. This is often the case for many smaller metal mines whereby a market can be found for more metal than the mine is able to produce (albeit this market is usually for variable and unpredictable prices). If funding is available, increased capacity is only warranted when there are adequate ore reserves and if an adequate return can be achieved on the investment necessary for expansion.

For very long-lived ore bodies, the limiting factor is not mine production (assuming funding would be available for desired expansion), it is the market. An example of this might be a Wyoming bentonite mine with very large reserves. Expansion of production is not warranted because larger penetration into the very competitive bentonite markets has not been successfully achieved.

Marketing people must be cognizant of the productive limitations of the mine and of the company. They must also be cognizant of the processing capabilities and other skills of the firm. They must not sell product that the mining company is not capable of producing or that is not feasible to produce.

The utilization of marketing research introduces the scientific method to mine marketing. As such, the more dependent a mining company becomes on marketing research, the less subject it is to the inefficiency and waste incurred by marketing efforts based wholly on past experience, intuition, and pure change (Nystrom, 1951). However, marketing research, when warranted by the size of the marketing effort, should be given well-defined goals within a well-defined budget. Much time and money can be inefficiently spent on prospective products for which there will be no adequate market or on markets that do not meet corporate objectives. Close coordination with all phases of the marketing mix is necessary in order to derive the most benefit from research.

There are many phases of marketing research that would be appropriate for some mining companies but not for others. Depending on the particular mineral or metal commodity (or refined product), as well as particular corporate objectives, the research effort should concentrate on different analyses. The following comprehensive list better defines the specific types of marketing research that can be undertaken (after Nystrom, 1951):

1. *Product Analysis.* This field embraces all applications of marketing research techniques designed to develop new products or adapt old ones so that they will have maximum acceptability to the user.

2. *Brand Position Analysis.* Current or periodic study of competitive volume of the different brands in a product field.

3. *Consumer Surveys.* Designed to determine the users of product.

4. *Sales Organization and Operation Research.* Time and duty analyses of sales activities; cost accounting analyses of operations of individual salesmen; studies of methods of com-

pensating sales personnel; and studies of sales training methods and procedures.

5. *Wholesale and Retail Distribution Analysis.* Studies of the various channels of distribution.

6. *Sales Record Analysis.* Internal analyses using the accounting records of sales as a foundation for solving a number of specific marketing problems.

7. *Distribution Cost Analysis.* Studies aimed directly at reducing the cost of distribution, which averages approximately 60% of the final cost of commodities.

8. *Quantitative Market Analysis.* Determines the amount of a commodity that a given market can be expected to absorb.

9. *Attitude and Opinion Research.* Used chiefly as a basis for public relations and advertising activities.

10. *Advertising and Sales Promotion Research.* Applying and developing marketing research procedures as a basis for developing and executing advertising campaigns.

11. *Price Analysis.* Measuring market demand at various price levels.

12. *Market Trend Analysis.* Observe and interpret changing conditions and forecast future market conditions.

Some of the above mentioned types of marketing research are better suited to manufacturers of consumer goods while others are better suited for producers of industrial commodities. However, all have been included because at one time or another, a comprehensive mine marketing research program would probably include at least parts of all the techniques listed.

PRODUCT

Products extracted from surface mines are varied in composition, grade, and possible coproducts or byproducts. This variability includes large mines producing high volumes of low-grade material, usually sold at relatively small profit margins. Examples may be a large molybdenum porphyry pit or a large iron taconite pit. The other end of the spectrum would be small surface mines producing low volumes of high-grade material that is usually sold at relatively high profit margins. Examples may include a small foreign mine extracting high-grade manganese ore from an outcropping vein to a small domestic mine extracting high-grade uranium ore from a sandstone outcrop.

After mine-run ore is extracted, it may be directly marketable or further upgrading and/or treatment may be necessary. Chrome ore and manganese ore are marketable directly from the mine as long as shipping grades exceed 44% Cr₂O₃ for chrome ore and 48% manganese (low impurities) for the latter (Anon., 1982). Steelmaking and chemical industries use these ores as raw materials. Certain lower grades of hematite, containing free silica, were beneficiated to merchantable grades by washing, although this is not common practice in the United States currently. Coal is cleaned and often graded to size in preparation for market. Note that the physical character of the material is not changed by such beneficiation process. Some types of treatment for market are more specialized, as with asbestos, which is cleaned, expanded, and graded carefully (Parks, 1957).

Many ores require transformation treatment between mine and the final market. Although most small, some intermediate, and a few large mines will sell their ore or concentrates directly to a custom smelter, the fact remains that the final market usually depends on a refined metallic product. Copper, lead, and zinc ores are typical of mine-run products that are milled, smelted, and ultimately refined (Parks, 1957).

Industry standard specifications for marketable metal, ore, alloys, and nonmetallics can be found in publications like *Metals Week* and *American Metal Market*.

Most ores and concentrates sold in the United States have standardized marketable production units in short tons (2000 lb). Notable exceptions, however, are iron ore, phosphate rock, and sulfur, which all have marketable units in long tons (2240 lb). Most foreign ores are sold on the metric tonne (2204.6 lb) basis. Refined metal, in the United States, is generally sold in avoirdupois pound units; precious metals (gold, silver, and the platinum group metals) are sold in troy ounces; and mercury is sold in 76-lb flasks.

It is very seldom that a mining company would be involved in the marketing of a totally new product. More than likely, this new product would be the modification of an already mined (either by the company in question or other mining companies) product. Examples might be a new standard length or a new standard diameter of refined copper wire, or the marketing (by a mining company) of minted silver coins (silver produced from their mines), or the marketing of a new size of crushed aggregate. However, discovering a market for a new product does occasionally happen. For example, a use may be discovered for a previously uneconomic mineral. (Natural zeolites, a relatively new industrial mineral with many unique marketable properties, is a good case-in-point.)

In any event, management should take the proper marketing evaluation steps (whether these be formal or informal) to ascertain economic viability of introducing the new or modified product. This product analysis should include some or all of the following: engineering development; pretesting; further engineering development; test marketing; go/no-go decision; and marketing plan. During this product analysis, cost estimates, price estimates, and life cycle estimates should be ascertained as accurately as possible. In this way, a proper economic analysis can be accomplished to establish the profitability of the new product as well as the expected return on invested capital to get the new product into production. The economic analysis is usually the culmination of all the preproduction efforts and is the mechanism by which management makes the final go/no-go decision for the new product (Rewoldt, 1977).

Ancillary decisions that often follow the introduction of a new/modified product are such things as packaging, warranty policy, and product service. Although often more appropriate for consumer products, the mining firm may want to brand and/or patent their new/modified product.

DISTRIBUTION

Once a sale is made, the product must be made available to the customer to be put to its end use. The overall distribution strategy should allow dependable product deliveries by the most efficient means, at reasonable cost. Distribution is often an area where seller/buyer problems, if any, materialize (Converse, 1964).

Generally speaking, the producer/seller must identify the distribution channels most effective for his select markets. These channels could involve direct sales to the customer or indirect sales by utilizing the services of middlemen. If distributors, wholesalers, retailers, or brokers are to be used, the appropriate ones must be recruited and incorporated in the overall distribution scheme.

Surface mined products of a high-margin, low-volume nature, will tend more toward the use of middlemen, at least more than the distribution of low-margin, high-volume products. This is due primarily to the fact that the former com-

modities are much less sensitive to transportation factors and hence are distributed over a much broader geographic area. High tonnage sales of products such as aggregates, trona, sulfur, potash, coal, and lime tend to be to more localized customers, or at least to a narrower portfolio of customers, which allows the more direct sales approach, without middlemen. There are exceptions to all cases, certainly, and the surface mine producers must be flexible enough to utilize the distribution channels most efficient for their own needs.

The aspect of physically transporting the product to a buyer is a very important one and can involve any of the basic transport methods via truck, rail, water, or air. The selection of the transportation mode is dependent on many factors, including product bulk, geographic location, distance to buyer, quantity to be moved, availability and accessibility to types of transportation, availability of loading and unloading facilities, freight rates, time frame allowed by buyer, nature of product, and many more.

Often the choice of transportation methods is very limited and may even exclude the benefit of competition (i.e., service available from only one truck or rail line). Fortunate is the surface mine producer who has his choice of several transportation lines, allowing a better chance for improvement on transportation costs. This also usually results in better service and more willingness by the entity providing the transportation to resolve any problems.

Then there is the age-old question of whether to utilize outside transportation services or provide them internally, such as buying and operating a fleet of trucks. Again, there are so many variables to consider for each site specific case but, generally, producers will not provide their own transportation unless careful studies clearly show economic advantage, especially considering amortization of investment. Chances are, however, unless the producer has no choice, normal available transportation services will be utilized.

Inventories can get out of hand, however, either by poor management or poor planning and can result in a rather large working capital requirement. Over the long run, inventory levels should be maintained just enough so that interruptions of dependable product delivery to the buyer are minimized or eliminated.

Assuming product specifications and quality control are maintained, proper implementation of product distribution is possibly the most important aspect of fostering repeat customers. But even under the best of conditions, problems can arise so policies need to be developed to resolve these situations.

PROMOTION

Buyer Behavior

Most surface mined products, whether they be high-margin, low-volume or low-margin, high-volume, are typically sold to such industries as manufacturing, construction, building, and fabrication. These sales transactions often involve middlemen such as brokers and distributors. If product sales are made directly to the buyer, this is usually done through departments of buyers and purchasing agents. The customer purchasing control during the buying process can be centralized or decentralized. It is important, then, to recognize that industrial buyer behavior is governed by stages of internal decision-making, the nature of which has to be understood in order to devise proper product promotion approaches. The number of decision-making stages, of course, varies from company to company and depends on the situation.

A customer's willingness to buy depends on the amount of product information he needs, the extent of availability of competition, the extent of available substitutions that will accomplish the same end use, and the thoroughness with which the buyer intends to research the possible purchase (Rewoldt, 1977).

The final product sale, then, can be as routine as taking orders over the telephone or it can be a very complex and involved approach, depending on buyer behavior during the purchase decision process.

Buyer behavior can be affected by the nature of the salable product. For instance, the final decision maker in a construction company that needs to purchase aggregate (low-margin, high-volume commodity) for a road building job may choose to purchase from an aggregate producer that did not have the lowest price bid. His reasons may simply be because that particular producer has an established presence and the credibility to produce the aggregate. This situation is one in which a dependable aggregate supply as an integral part of the overall construction program is absolutely essential for the construction job to be successful. On the other hand, a purchasing agent buying copper for a fabrication plant may make his purchase decision based on price alone due to its circumstances and indifference to the kinds of concerns that bothered the construction company. Recognizing these different characteristic commodity effects on buyer behavior will help the seller to promote his product. The aggregate producer should promote his past track record and emphasize his ability to perform dependably. The copper company wishing to sell to the fabricator should know that the sale depends almost entirely on offering the lowest price.

There is a tremendous amount of logistics involved in coordinating the product distribution cycle and, depending on the size of operation, a lot of information has to be processed, stored, and scrutinized. The computer can greatly facilitate the handling of this information. If no in-house computer is available, then outside services (such as time-sharing using a remote terminal to access a computer owned and maintained by a service company) can be used. Production, inventories, costs, customer lists, etc. can be accommodated nicely by computer and, properly implemented, can keep track of enough variables and consolidate information in such a way as to allow better chances of improving overall efficiency. Even small producers can take advantage of today's relatively low cost computer packages available for standard business needs. Again, site specific circumstances will dictate whether data processing services would be cost effective.

One of the major factors in the product distribution chain is the maintenance and management of product inventory. Ideally, product inventories would be kept at zero, with deliveries scheduled directly from production. Obviously, this is impossible because the real world is not ideal and, in fact, is subject to a myriad of practical considerations and problems of getting a product from the production department to the end user. A *buffer* is needed to accommodate this inability to perfectly match production rate to customer demands, and hence inventories are a necessary part of the equation.

Promotional Strategy

Unless a surface mine operation is producing a commodity that is in constant demand and has a shortage of supply, some effort is going to have to be expended to promote the product to increase chances of a sale. Sales promotion, then, is the presentation of product knowledge to

prospective buyers to whatever degree of detail is needed. It can also, and often does, involve a propaganda approach in an attempt to predispose the buyer to a favorable consideration of a producer and his product(s) (McGarry, 1964).

Propaganda to persuade customers to buy products can occur via advertising and/or personal selling. Advertising depends heavily on communications media and often on psychology. The psychological ploy appeals to either reasoning or emotion or both.

Most advertising for surface mined products is done through mining publications and brochures and tends to be directed at the psychology of technical reasoning, such as promoting products of good quality control, dependable delivery, and suitable specifications. Even the personal selling approach emphasizes the technical reasoning aspects because decisions to buy mining commodities usually depend on the relative economics of selecting a commodity from one competitor or another. This economic equation for the buying decision often involves much more than just price.

The aggressiveness with which products are promoted and the budget appropriated for this program are dependent on several things including the seller's philosophy, type of product, and current market conditions. One producer may treat product promotion as an investment and another may consider product promotion expenditures to be cost of product sold on a unit basis.

Depending on the nature of surface mined products to be sold, a fair amount of promotional attention is frequently given to product identity. Once a product identity is established and can be related to a good track record of reliable performance, then subsequent sales promotions can utilize that product name or identity to enhance future sales and to draw comparisons to promote other products from the same producer.

If a mine producer's products are of a nature that can be utilized by distributors or manufacturers, often the established presence of these entities and their product identities indirectly benefit their raw material suppliers (in this case the surface mine producer). This is because their raw materials are promoted for them, perhaps in a remanufactured or blended form, but promoted nevertheless.

PRICING

Exchange Prices

The subject of pricing and prices is exceedingly complex, especially when dealing with the intricacies of mining commodities. Many of the commodities are very cyclical in nature and the profits of many mines are intimately tied to the ups and downs of the economy. Some commodities have very extreme price swings during a business cycle, especially base and precious metals. Thus, these industries may experience a period of one or two years of very high profits only to weather an extended period of low profits or even excessive losses.

Some commodities, such as coal and uranium, for the most part are sold under medium- to long-term contractual arrangements. In this way the producer is guaranteed a stable market and prices while the buyer is guaranteed a stable source of supply.

In the world metal markets, most metals are sold through exchanges. In London (and there are counterparts in other large European cities) metals are usually sold through the London Metal Exchange (LME). This exchange has many member firms specializing in the purchase and sale of metals in all of their forms, as well as various other mineral commodities. In general, the functions of this exchange are very

similar to those of the United States' grain exchanges. That is, there are traders seeking the best advantages and protection against price fluctuations (Anon., 1968).

Although spot (immediately deliverable) metal is available, the mechanism of sale on the LME is usually the futures contract. In this contract, a buyer purchases a warrant for so many metric tonnes of a metal (which are not necessarily available at the moment) for delivery at some time in the future, usually three months hence. The price offered for the metal will be different, usually not lower, from the prices offered for spot delivery (prices are quoted in pounds sterling per metric tonne). Such contracts are negotiable in the same way as spot metals. By trading these futures contracts, traders again seek protection against unfavorable price swings by hedging against current sales. Suppliers, such as smelters, also use the device to help smooth out production schedules, at prices that have near-term assurance (Anon., 1968).

The London Metal Exchange often sets the current prices for Europe and much of the world. Its publicly quoted prices represent the actual purchases recorded from day to day.

On the North American continent there is no centralized metal exchange in the same sense, though the Metals Section of the New York Commodity Exchange (COMEX) does handle some volumes of metals entering commerce in the United States. The COMEX does trade commodities futures contracts for copper, gold, and silver. (Other exchanges trading in metals are the New York Mercantile Exchange which trades in platinum futures, and the Chicago Board of Trade, which trades in silver futures.) Some primary producers of copper base their cathode price on formulas incorporating specific COMEX copper futures contract prices (Anon., 1982).

The commodity futures markets in the United States are similar to futures markets in London and elsewhere. In US markets, people and/or firms purchase contracts that guarantee the delivery of a standardized amount of a metal at a certain price on a certain future date (contracts can be purchased up to two years forward). People participating in the futures market are generally classified as either speculators or hedgers. Speculators buy contracts *long* (anticipating a rise in price) or sell contracts *short* (anticipating a decline in price). If the speculator has correctly anticipated the subsequent rise or fall in price (i.e., subsequent to his *long* purchase or *short* sale of a particular metal futures contract), he will profit; if the opposite is the case, however, then he will experience a loss. Hedgers, unlike speculators, buy and sell futures contracts in order to avoid the risks associated with price fluctuations. In this way hedgers, being actual producers and consumers of specific commodities, ensure they will be able to deliver or to receive a specified quantity of a commodity guaranteed at a predictable price (Aronson, 1979).

Contract Prices

Most metal sales in this country are, however, generally effected through private contracts, though through much the same pattern of brokers as exists at the LME, many of whom are highly specialized metal traders. Producers may refer to *Metals Week* for price quotes (a subsidiary publication of *Engineering and Mining Journal*), which is functionally the US counterpart to the LME's price quotes. This service gathers data on virtually all major minerals commodities sales made in the United States, and is thus able to publish authoritative average prices in daily, weekly, and monthly terms. In some metals, *Metals Week* collaborates with specialized trading companies, such as Handy and Harman, Inc.

who predominate in dealings in silver and other precious metals (Anon., 1968). *Metals Week* is an excellent source of price quotations for base, precious, and miscellaneous metals as well as for different ores and concentrates, ferroalloys, and many industrial and nonmetallic minerals. Another major source for price quotes is the authoritative publication *American Metal Market*.

New Pricing

When trying to establish a price for a new product (i.e., a product for which there is no established price) such as a new specification of a particular industrial mineral, cost-based pricing has many advantages. This type of pricing is explainable, understandable, justifiable, predictable, politically acceptable, and widely used. Properly used, it can be salable and profitable (Bailey, 1978).

Other factors that should enter into the pricing decision of a new product are market conditions, prospective competitive pricing, anticipated growth rate of the market, anticipated market share, and the market's expectations of prices and its ability to pay. Pricing policies for the new product have to be considered. Will pricing discounts (quantity, functional, trade) or advertising allowances be offered? Will the new price take into account the trade channels for distribution of the new product?

Legal Considerations

When establishing any pricing, a mining company has to be aware of all of the possible legal pitfalls. Antitrust has always been one of the most important legal considerations affecting major industrial pricing strategy. Officials of the Department of Justice have become increasingly more critical (through enforcement by criminal prosecution) of antitrust violations such as price-fixing and *predatory economic conduct*. Prudent management should give greater attention to avoiding involvement in antitrust proceedings. One such area is price leadership. When increasing the price of a product, it is the leader (usually a company with a large market share) which takes the risk of severe governmental scrutiny. The price leader should be prepared to explain its actions to a Congressional committee or some other investigating body.

Another trend in antitrust enforcement involves what can be described as *price signalling* or *price-fixing*. For many years, it was understood that a price-fixing conspiracy required an element of common understanding among competitors. However, more recently, a meeting in which one party expressed his intention to increase prices while another party sat quietly by and then later increased his own price has been found by juries to constitute this necessary element of common understanding. For this reason, lawyers frequently advise clients to avoid, or at least to document, meetings with competitors and to make a dramatic exit from a properly scheduled meeting that veers into forbidden waters (Bailey, 1978).

Another legal area that should concern mining company management is price discrimination. Although price discrimination is an area of law more frequently applicable to consumer products cases, it also has some application to the pricing of industrial products. Price discrimination is restricted under the Robinson-Patman Act and has been criticized in recent years for fostering undue price rigidity. Despite this apparent pricing rigidity, the statute still enjoys considerable support in Congress, and may be enforced by injured parties even if government enforcement is limited. Thus, violations (or alleged violations) of the Act may be subject to civil lawsuits even if there is no challenge by the government (Bailey, 1978).

8.7. Surface Mining Control and Reclamation Act of 1977

DAVID S. HEMENWAY

INTRODUCTION

This section presents a discussion of legal counsel's role in the government regulatory area dealing with mine land reclamation with specific reference to coal mining. The Surface Mining Control and Reclamation Act of 1977 (Act) has had a dramatic impact on the coal mining industry. It is not the intention to present here an indepth analysis of the legal implications of the Act, but to present an overview of the lawyer's role in assisting coal mine operators in complying with the requirements of the Act and regulations.

It seems helpful to understand the role of the other disciplines in an undertaking such as compliance with the Act. Hopefully the nonlawyer reader will have a better understanding of the assistance and advice that legal counsel can provide. The lawyer reader will be struck by the superficial treatment given the subject. In that vein, it was sought to direct counsel to sources of knowledge and not to provide that knowledge here which could well fill a legal treatise.

COMPLYING WITH THE ACT'S REGULATIONS

Permitting

Early participation by counsel in the permitting application process, not only in the legal facets described subsequently, but also in identifying the studies and the like which may be necessary is imperative. For example, extensive environmental studies may be required in the early stages in order to secure a sufficient baseline data.

Counsel should understand the corporate structure of the operator in undertaking the legal facets of the permitting function. Sec. 778.13 (all references to final EIS, Vol. III, "Draft Final Regulations," *supra.*) provides a detailed informational reporting requirement concerning corporate structures including names and addresses of officers, directors, and principal shareholders. It further requires legal ownership of lands contiguous to the permit area be identified and reported.

Sec. 778.14(a) provides for a disclosure of expense relating to suspension of permits and revocation of bonds for a five-year period preceding the permitting application. If such has occurred a detailed report is required (778.18(b)). A listing and status report is required for all violations issued by any government agency of reclamation or air or water environmental protections by the operator, its subsidiary, affiliates, or persons controlling the operator (778.14(c)).

Documentation of the legal right to conduct mining operations on the permit area must be submitted and where the mineral estate is severed from the surface a consent form executed by the surface owner must be provided if a surface mining operation is planned (778.15). In addition, the Act describes certain land areas as unsuitable for mining and provides that other land areas may be unsuitable if certain criteria are met (521 Act). If such unsuitability proceedings or impacts are present, (Parts 761, 762, 764, and 769) a status description plus compliance with the respective requirements must be submitted. (See also Sec. 510(c) of the Act.)

One other significant consideration which needs early attention is the method the operator intends to use in financing the mine operation. Sec. 506(b) of the Act provides that the maximum permit term of five years *may* be extended by showing an extended period of time is necessary to obtain financing "for equipment and opening of the operation." Documentation from the source of the funds is necessary to support an extended permit term (778.17). Bonding and insurance requirements must be met when submitting the permit application (778.18, see Part 860 as amended and Sec. 509 of the Act).

To obtain data on the informational requirements of the Act counsel should review Sec. 507 which contains informational requirements and Sec. 508 which sets forth the reclamation plan requirements. A checklist can be formulated to make sure that in the initial stages no subject is overlooked. This process can be extremely helpful as the state application form may mask the specific identity of the subject matter. The performance standards of the Sec. 515, surface, and Sec. 516, underground, and Parts 816 and 817 of the regulations should be reviewed in order that the reclamation plan addresses those requirements. Finally, each state's regulatory program needs a subject matter view for purpose of identifying additional or unique treatment of subjects.

Due to the fact that most states have implemented permanent programs, the initial permanent permitting process is now underway. The operator has two months from the date of the state program approval to submit an application. A permit is required within six months to continue operation. There are procedures to avoid the harsh result of being forced to shut down due to the state's inability to process a timely filed "complete" application. These include permitting additional acreages during the interim program and a two-tier review process. (See also part 773.) However, one development arising out of the identification of the problem may enable the operator to achieve a savings in cost and time. The state agency and other permittees may have submitted environmental studies which may provide beneficial baseline and other data which may be subject to incorporation into the studies the operator needs to perform. This may also assist in the identification and selection of consultants to perform studies not within the inhouse capabilities of the operator.

After review and planning has been accomplished, counsel may propose a meeting with the state regulatory authority. At this meeting, a description and a general outline of the studies and other aspects of the mine project can be given for reaction. Counsel also can achieve a clarification of any issues concerning legitimacy of the information requested. In this way, the operator can ascertain any areas where emphasis or additional studies need to be undertaken. These officials are the people who will review the application and issue the permit; therefore it is desirable to open lines of communication at an early date. The operator's personnel, including counsel, may seek advice from his counterpart representing the agency. This action may help avoid pitfalls and unfortunate conditions being placed on the permit.

To this point our discussion has involved no unique prob-

lems such as whether the operation in question is subject to jurisdiction and regulation. This question most frequently arises with a tippie or coal processing facility which is situated at a considerable distance from the mine operation and which is not an adjunct to a given mine (785.21). Other unique areas which should be given careful consideration include steep slopes (Appalachia 785.15), prime farmland grandfather (Midwest 785.15) and alluvial valley floors (West 785.19). These matters have all been subject to the litigation process (*supra.*) and it is recommended that careful scrutiny of those matters and administrative determinations by the Office of Hearings and Appeals be pursued.

During the preparation of the application and underlying supporting documentation, it is desirable to review progress in those areas. Legal questions which are bound to arise can be identified and a response made. In addition, counsel should make certain all legal records and documentation have been reviewed for accuracy. Contact should be maintained with the operator to ascertain any changes in the violation history, the operator's structure, and officers and directors who must be identified in the permit application.

Finally, when the permit application package is complete, a thorough review should be made by counsel to determine that all subjects have been appropriately covered and that there are no inconsistencies within the application. The agency review process including the public notification and participation features should be scrutinized during this evaluation (773.13, *et seq.*).

Upon issuance of the permit counsel should immediately review with the operator all conditions and requirements imposed by the regulatory authority. The conditions or requirements of the permit are subject to administrative and judicial review. The operator may seek to have conditions of the permit invalidated (775.11, *et seq.*). (See also 43 CFR, Part 4.) This means that unlike MSHA and similar to the NPDES permitting, a permit holder may seek judicial review of a permit condition which is deemed not lawful or inappropriate under the circumstances.

Compliance

When a viable permit is secured, the next area of concern is educational. Participation by operations personnel in the permitting project varies greatly. In most instances, that participation is minimal. It is imperative that operations personnel fully understand the requirements of the permit and the regulations governing the mine operations at the earliest possible date. Hence, a presentation to these personnel on the permit's conditions and terms and the regulations governing the operations must be undertaken. Counsel should be prepared to participate in the area of compliance and to respond to questions involving interpretations of the permit requirements.

The need for early understanding by operator personnel cannot be overemphasized. Remember the new permit holder occupies somewhat the position of the "new kid on the block." The regulatory authority may make early and frequent inspections to insure permit compliance. Initial compliance failures may cause the regulatory authority to conduct more aggressive and frequent inspections.

Operator personnel should be requested to avoid the temptation to make legal interpretations of the permit conditions or regulations. Rather they should be encouraged to consult with counsel immediately upon identifying any question of interpretation. Counsel by the same token needs to respond to those inquiries in an expeditious manner with short reasoned answers. Counsel must understand operations

personnel have no need for lengthy and learned discussions—precise and to the point responses are needed.

Another area of compliance assistance which counsel might propose is the use of an internal compliance team. This team would be composed of nonmine personnel having disciplines in the major permit areas, e.g., environmental (water), reclamation, and legal. This team would routinely visit the mine and perform an inspection. A conference can then be held with operations personnel. Here detailed corrective measures for problem areas can be discussed and an understanding reached as to problem areas and proper corrective course of action. Counsel can provide not only legal guidance, but may act as a mediator if disagreements arise.

There are disadvantages to formal procedures. Informal consultations between the disciplines and operating personnel may prove more effective. The temptation of nonmine personnel to impose their precepts of mining procedure on operations personnel is lessened through an informal structure. Finally, the necessity of maintaining open communications between these personnel is lessened in the formal procedure as the critiques which necessarily will arise may not be received with great enthusiasm by the mine. Counsel should advise the operator as to the pros and cons of such a procedure. The results of government enforcement however may dictate the advisable procedure to implement.

Enforcement

In the area of enforcement, counsel's participation is probably most evident. The responsibility here is somewhat negative in nature. It is either to reduce by degree and/or tenor a sanction or void the sanction. It is negative in that it does nothing in a positive fashion to enhance operator production or profit. The adoption of defined procedures and identity of responsibilities will help to alleviate the negative impact of enforcement.

Counsel should be familiar with the sanctions provided by the Act, the federal and state regulations. The federal and state regulations will not be dissimilar; hence all references are to the Act and the federal regulations. The permanent regulations dealing with enforcement were not a part of the overall repromulgation of permanent regulations. Applicable federal requirements are found in the Act at Secs. 517, 518, 521, and 525 and in the regulations at 30 CFR Parts 840, 842, 843, and 845. (843.11 and 843.12 were amended after publication of the CFR revised 1981 edition.) OSM inspectors and state regulatory inspectors have a right of entry on the mine property without a search warrant (517(b)(3)). Citizens who have filed a complaint may accompany an inspector but only to visit those areas which were the subject of the complaint (517(h)).

The Act provides four enforcement sanctions which may be imposed by the state regulatory authority. They are:

Notice of Violation: A notice of violation requires abatement of the violation within a set time period. A civil penalty of up to \$5000 may be imposed if corrective action is not taken by the operator. The amount is determined on the basis of the negligence of the operator, gravity of the violation, history of violations at the mine, and the good faith exercised in abatement.

Cessation Order: A cessation order requires cessation of mining activities on the area affected until abatement of the violation has occurred (521(a)2,3). A cessation order is issued if a violation has not been abated within the time set in a notice of violation, if the condition or practice creates an imminent danger to health or safety of the public, or is or can be reasonably expected to cause significant imminent

environmental harm (regulatory definition of terms found at 701.5). A penalty must be assessed if a cessation order is issued based on the above criterion.

Suspension or Revocation of the Permit: If a series of violations caused by the unwarrantable failure of the operator is found by the regulatory authority to exist, then a show/cause order is issued as to whether a permit should be suspended or revoked.

Injunctive Relief: Injunctive relief may be sought by the regulatory authority for interfering with inspections or for failure to comply with any order of the regulatory authority (521(c)).

In the event a cessation order is issued, mine personnel should be informed of their right to an informal conference at or near the mine site (521(e)5). A judgment should be made as to whether such a conference is desirable under the circumstances.

It is to be noted that if an informal conference is not held, the cessation order expires after 30 days of issuance. However, it should be borne in mind that nothing would prevent an inspector from reissuing a new cessation order at the time the old one expires.

Counsel should advise the operator when an inspector enters the mine property (usually he reports to the mine office); a qualified individual previously designated by the operator should accompany the inspector on his rounds. This individual should be versed in the mine operation, the permit terms and conditions, and should be able to explain in detail various reclamation activities. Frequently an apparent violation is reversed once an explanation of the mining or reclamation operation is made. In this way, the cost and expense of legally contesting the notice of violation or cessation order is avoided. The designation of key individuals to accompany the inspector should instill a cooperative and creditable relationship as distinguished from the adversary relationship which could arise.

A procedure should be adopted whereby the mine notifies counsel immediately upon receipt of a notice of violation, a cessation order, and if they are served with an order to show cause as to why the permit should not be suspended or revoked. A report form completed by the person accompanying the inspector serves this purpose. The circumstances surrounding the violation and the penalty assessment elements of negligence, gravity, history, and good faith abatement should be described on the form.

Upon a receipt of the notice or order and the report form, counsel can begin an investigation of the conditions and circumstances surrounding the incident. Counsel should ascertain whether the cessation order meets the statutory test of immediate danger to public health or safety or is of significant imminent environmental harm. Appropriate recourse through an expedited hearing with the office of hearings and appeals is available (525(c), 43 CFR 4.1180, et seq.).

In most instances, seeking of expedited relief may not prove productive. The next step is to await receipt of the penalty assessment. At that time, the operator has a right to request an informal conference with the regulatory authority. Exercise of this right stays the 30-day time limit on requesting a formal hearing. Informal conferences may serve as a productive means of achieving either a mitigation of the penalty or completely avoiding it. Preparation for conference should be thorough. A knowledgeable person from the mine should accompany counsel to the conference. As penalty assessments are levied on four elements—negligence, gravity, history, and good faith abatement—it is desirable to present mitigating evidence on the elements in the categories.

If the conference results do not prove successful, then the next step would be to request a formal hearing. At this point it would be treated as any other administrative appeal or court case in that normal trial preparation and conduct is available. The only exception to this is that the administrative law judge must follow the regulatory authority's point system in assessing penalties (43 CFR 4.1157). In essence so many points are charged for each element and then totaled. The total points are then converted to dollars of assessment (e.g., see 845.14). Also at the time notice of contest is submitted and a formal hearing requested the penalty must be paid. A refund will be made if the assessment is lowered (518(c)).

CONCLUSION

In conclusion, there are three areas where counsel participation could prove helpful. These are:

Permitting: includes the compilation of compliance, operator's structure, and land ownership information and oversight, guidance, and in remote cases, advocacy.

Compliance: is primarily to avoid enforcement problems through education.

Enforcement: the primary role is as an advocate and negotiator on behalf of the coal mine operator.

In performing these responsibilities, counsel must bring with him an understanding of litigation and the regulatory activities which have transpired. Particular emphasis should be given to the litigation of the regulatory programs promulgated by the Office of Surface Mining and to the ever-changing content of the regulations themselves. In this fashion, appropriate and able advocacy may be more readily available.

The nonlawyer reader may have a better understanding of the reasons for counsel's advice and the fact that some advice may have to be of a qualified nature. Hopefully, the reader has been convinced of the need for an open dialogue between the operator and counsel at an early date. Finally, the need for early and thorough preparation by counsel and the operator should be emphasized.

8.8 Purchasing and Inventories

DANIEL P. PLUTE

MATERIALS MANAGEMENT

Many mining and processing companies find that material and spare part costs account for 40 to 60% of their operating and maintenance budgets. They also find that the capital invested in inventory to support the mining venture runs into the millions of dollars—money that may be nonproductive and often wasted if not properly managed.

Maintaining higher than required inventory balances ties up capital; keeping a low balance increases the risk of prolonging equipment downtime or production delays. The key is defining the proper mix, the correct balance, planning purchases to meet production and maintenance schedules, and locating assured sources of supply with reasonable prices and acceptable service.

Managing the purchasing, inventory, and warehousing functions requires that each area be accountable and responsible for its activities. The following responsibility statements work well in industry:

1. *Purchasing*—The role of Purchasing is to provide materials requested by Operations and Maintenance and Inventory Management at the required time, at the lowest possible cost. Cost consideration must include the price of the materials, the cost of transporting it to its destination, and the cost of the clerical and paperwork required to order, receive, store, issue, and pay for the materials. Purchasing often determines which vendor is to be used and may switch vendors to obtain a better price.

Purchasing does not have the authority to substitute a different item or different brand to obtain a better price or delivery time without the approval of the user. It is absolutely necessary that Purchasing work closely with the user so that the user can make appropriate decisions relative to the tradeoff between purchase price, delivery time, item specifications, and quality.

2. *Inventory Management*—The role of Inventory Management is to request material for stock in a timely manner and in quantities that provide the best level of support to users at the lowest cost. Inventory Management establishes the rules that determine when an item is to be ordered and in what quantity. They work directly with Maintenance and Operations in determining what items are to be stocked. Maintenance provides them with projected usage information for normal stock items and minimum stock levels for critical and insurance items.

3. *Warehousing*—Warehousing's responsibility is to receive, store, issue, and deliver materials to users efficiently and to prepare accurate transaction documents for these functions. It is the responsibility of the warehouse to develop and adhere to adequate procedures for the receiving, issuing, storing, and securing materials. The warehouse is responsible for keeping accurate records on all material within its purview.

4. *Operations and Maintenance Requirements for Spare Parts*—The responsibility of operations and maintenance is to communicate in an accurate and timely manner to Inventory Management and to Purchasing what their requirements are for spare parts. For parts used on an ongoing basis, they will communicate to Inventory Management any expected changes from normal usage patterns and any new

items which should be maintained in warehouse stock. They also work closely with Inventory Management in the analysis of slow and nonmoving items to determine what items can be sold as surplus or declared obsolete. In case of an emergency requiring exceptional purchasing activity and followup, they work directly with Purchasing providing them with information to help them obtain the material required.

Operations and maintenance personnel deal directly with vendor representatives in determining an item's specification, application requirements, and what items can be substituted for standard items.

DETERMINING SPARE PARTS AND MATERIAL REQUIREMENTS AND MANNING LEVELS FOR A MINING VENTURE

The amount of capital required for the inventory of spare parts and operating supplies will vary with the mine type, the distance from the supply centers, production and operating plans, the rules developed for reordering and the quantity to be purchased, and the maintenance program used at the property. Normally, 4 to 7% of the capital cost of the fixed plant and equipment is allocated for inventory investment.

The manning level required will also vary with the mine and ore type, processes included, production plan, operating schedule, and type of information processing system. Fig. 1 shows Materials Management Statistics for several North American mining companies. It includes information by mine and ore type, production levels, purchasing and warehousing statistics, manning levels, and performance of employees.

Selecting the Initial Complement of Spare Parts and Operating Supplies for New Properties or Property Modification

The initial selection of spare parts and operating supplies should begin after the Request for Expenditure (RFE) has been approved. A work plan and critical path schedule should be prepared to monitor project activities and track key completion dates.

The responsibility for selecting the inventory item mix should be assigned to key maintenance, operations, and inventory management personnel. Final selection approval should come from the mine manager, senior financial personnel, and the materials manager.

Factors to consider in the spare part and operating supply selection should include:

- Equipment availability and operating goals.
- Capital availability.
- Equipment manufacturer's spare part recommendations.
- Previous experience of Maintenance and Operating Managers.
- Experience of other mining companies with similar equipment and conditions.
- Management review of Process and Instrument drawings to identify critical backup requirements.
- Consumption estimates for chemicals, reagents, and operating supplies.
- Wear-life estimates for major material such as liners, refractories, grinding media, and belting, etc.

Operating supply and spare part availability and vendor lead time projections.

Availability of storage space.

The inventory item identification process must include activities to determine the initial purchase order quantity and delivery date, to estimate annual requirements, and to define application or minimum quantity requirements.

Defining Stock Level Requirements for Inventory Items

The Inventory Management supervisor is responsible for determining when to order and the quantity to purchase for all inventory items.

The Inventory Department should process the approved inventory item requests and determine when to review the item for reordering (the reorder point); calculate the suggested order quantity (the economic order quantity); determine the items' category (i.e., bearings, haul truck, shovel, crusher, mill, etc.); and the catalogue and ordering description for the item.

Estimated usage figures and vendor lead time projections, included on the new stock item request, can be used for the calculations. After six months usage history has been captured or when production or maintenance plans change, the safety stock, reorder point, and economic order quantity levels should be adjusted.

Production and maintenance plans should be used to determine actual quantity and delivery date requirements for items consumed in the production process and for spare parts used in planned maintenance programs. Quantity and delivery date projections should be modified when plans change.

The Inventory Department should also calculate the average and maximum stock levels, and prepare budgets for the inventory investment and new stock item requests. Monthly, actual, and budget comparisons should be made to identify variances from plan.

The calculations for average and maximum value levels are:

$$\begin{aligned} \text{Average inventory value level} &= \text{safety stock quantity} \\ &\quad + \text{one-half of the economic order quantity} \\ &\quad \times \text{unit price} \\ \text{Maximum inventory level} &= \text{safety stock quantity} \\ &\quad + \text{one economic order quantity} \\ &\quad \times \text{unit price} \end{aligned}$$

Determining Warehouse Size Requirements and Location

The warehouse facility should be attached to, or located near, the maintenance shop. The Maintenance Department is the largest user of warehouse service; therefore, locating the warehouse near the maintenance shop area will reduce idle and spare parts transportation time.

The amount of space required for inside storage will be influenced by the mine production plan, weather conditions, and the number of items planned for the inventory mix. Heated and cold storage areas may be required.

For estimates on inside and outside space requirements, allow 0.2 m² (2.2 sq ft) per line item for inside storage and 0.4 m² (4.7 sq ft) per line item for outside storage; pallet rack storage, allow 1.2 m² (13.1 sq ft) per pallet rack.

Aisleways and material handling equipment routes should be spaced so that equipment can be moved easily and safely. For large equipment, i.e., 1814-kg (4000-lb) forklifts, a 1.8-m (6-ft) aisle will be required while a 0.9-m (3-ft) aisle should be planned for walkways. A large aisleway 1.8-m

(6-ft) should be provided for moving material handling equipment between the receiving and issue areas.

Storage Bins, Storage Location Codes, and Warehouse Security

A mixture of storage drawer modules, storage bins, and pallet racks will be required. A ratio of 50% modules, 30% bins, and 20% pallet racks can be used for estimating.

The modular cabinets should be located near the issue window and used for storing smaller fast-moving items. The bins should be situated next to the modular cabinets. The pallet rack area should be situated near wall exposures and near the receiving station.

The modular cabinet and storage bin aisleways should face the issue window for easy access to storage areas.

Storage location codes and row content labels should be placed at the end of rows. The row content labels should include a brief description of row contents, i.e., Row 1—Unit Rig M100 and the number of bin or cabinet sections.

Storage location codes should include designations for warehouse area, row, section, shelf, drawer number, and bin number. Number codes should be used.

Bin labels should be affixed to bin areas and should contain information on item descriptions, part number, equipment type, where used, and the computer number.

Warehouse storage areas (inside and out) should be secured and have controlled entry. Items subject to pilferage, i.e., tools, automotive tuneup parts, etc., should be stored in a locked cabinet.

Adequate lighting is essential to good housekeeping and identification of items.

MANAGING THE CAPITAL INVESTED IN SPARE PARTS AND OPERATING SUPPLIES

Millions of dollars are committed to purchase and maintain spare parts, components, and operating supplies. Often, the dollars are mismanaged. Capital is invested in overstocked supplies and spare parts; on the other hand, investment levels that are too low increase the risk of production losses and may contribute to underutilization of maintenance labor.

An optimum inventory investment level can be reached by planning material requirements using maintenance schedules and production plans and by analyzing historical usage and cost information to project needs.

The programs that manage the inventory investment and material and supply costs must be flexible. They must contain features that allow rapid adjustments commensurate with changes in mining plans and increases or decreases in production levels. Materials management must adjust its strategy as economic and operating conditions change.

To achieve its goal, materials management must have the correct set of *tools* that will allow it to make timely adjustments to its business plan, minimize the capital required to purchase inventory spare parts and operating supplies, and to purchase the required material on the required date at the lowest possible cost. The following programs are recommended:

Material Requirements Planning

Mine, maintenance, and processing plans are used to determine spare part and operating supply requirements for the short term. Adjustments to purchase commitments are made as the plans change—delivery dates and order quantities are modified to meet current requirements. An economic evaluation is made on the feasibility of cancelling the purchase order or reducing stock levels.

Successful use of material requirements planning requires a strong communication link between operations, maintenance, and materials management. Purchasing must relay information on delayed deliveries to maintenance so that planners and schedulers can adjust their maintenance plan, and operations must advise inventory management on changes to production plans so that inventory requirements and inventory levels can be adjusted.

Inventory Stratification

Inventory items are stratified into categories and classes to improve inventory management capabilities. The categories are active and inactive—the active classes are *A*, *B*, and *C*; the inactive classes are *X*, *Y*, and *Z*. The active classes are determined by the annual usage dollar amount, the inactive items by the dollar value on hand. (Active items are items with issue activity during the last 12 months; inactive items have no issue activity during the last 12 months.)

The active and inactive item categories and their dollar parameters are:

Active Item Class	Annual Usage Dollar Amount
<i>A</i>	Exceeds \$1500
<i>B</i>	Between \$500 and \$1500
<i>C</i>	Less than \$500
Inactive Item Class	On-Hand Dollar Value
<i>X</i>	Exceeds \$500
<i>Y</i>	Between \$300 and \$500
<i>Z</i>	Less than \$300

(The usage value and on-hand value parameters may vary.)

A items represent approximately 5 to 8% of the active, high-usage-value items; comprise 40 to 60% of the active item inventory investment; and account for 70 to 90% of the dollars spent annually on material.

B items are the intermediate-usage-value items representing 10 to 20% of the active inventory investment and account for 10 to 20% of the dollars spent annually on material.

C items represent 75 to 80% of the active items which have less individual effect on inventory investment. As a group, they represent approximately 15 to 25% of the active inventory investment and account for approximately 5 to 8% of the dollars spent annually on material.

X items represent 10 to 15% of the high-inventory-value inactive items and account for 70 to 80% of the inactive inventory investment. These items offer the greatest opportunity for recovery of investment through internal use or other disposal.

Y items are of secondary importance and represent 15 to 25% of the inactive inventory investment, accounting for 25 to 35% of the inactive items.

Z items represent approximately 60 to 70% of the relatively unimportant low-inventory value items and offer the least opportunity for investment recovery because of the substantial clerical cost required to analyze so many items of low individual value. *Z* items account for approximately 3 to 5% of the value in the inactive inventory.

Once stratified, different controls and programs should be used to manage the categories and classes.

Active Item Management

Economic Order Quantity—The economic order quantity balances the costs of preparing purchase orders and carrying inventory. The economic order quantity is a suggested order

quantity and should be adjusted for vendor packaging, for actual quantity requirements, weight required for C/L or T/L shipments and for quantity discounts in some situations, etc.

One formula for calculating the economic order quantity is:

$$\text{EOQ in dollars} = K \sqrt{\text{annual usage dollars}}$$

$$\text{EOQ in units} = \text{EOQ\$} \div \text{unit price}$$

$$K = \sqrt{\frac{2B}{I}}$$

where

B = cost of preparing purchase orders (line item)

I = cost of carrying inventory (decimal)

Costs to consider in determining purchase order and inventory carrying costs include:

Purchase Order Costs (line item)
Purchasing forms
Salaries
Telephones
Telex
Computer costs
Envelopes
Mailing
Purchasing department operating costs
Inventory Carrying Costs (decimal)
Cost of capital
Storage costs
Deterioration and obsolescence
Insurance
Warehouse salaries

In the mining industry, a *K* factor between 3.5 and 6 is considered normal. For new operations and operations converting to the economic order quantity system, an initial *K* factor of 6 is recommended. After six months of use, the *K* factor should be reduced gradually to a factor of 4 or to the factor calculated by the formula (Figs. 2 and 3).

Reorder Point and Safety Stock Levels: Historical or estimated usage information (new items), vendor lead time, the items' class, and safety stock factors are used to determine the stock level at which the item should be reviewed for order action.

The formulas for calculating safety stock and reorder point levels are:

Safety Stock

$$\text{Safety Stock} = \text{Safety Stock Factor} \times \text{Lead Time Usage}$$

Safety stock is that portion of the inventory maintained as a buffer against delayed deliveries or an erratic demand pattern. It can be expressed in months, weeks, or days of usage and should vary according to the lead time and classification of the item.

Safety Stock Parameters

If lead time is	Items	Safety stock factor (of lead time use)
Over 10 weeks	<i>A</i> and <i>B</i>	0.60
	<i>C</i>	0.80
6 to 10 weeks	<i>A</i> and <i>B</i>	0.50
	<i>C</i>	0.70

**Fig. 2. Inventory Model Current Practice
(Order Items Six Times per Year)**

Item Class	Number of Items	Annual Usage Value	Line Item Orders	Order Value	Average* Inventory Value
A	200	\$500,000	1200	\$417.00	\$41,700
B	300	60,000	1800	33.00	4,950
C	1200	27,000	7200	3.75	2,250
	1700	\$587,000	10200		\$48,900

Application of economic order quantity concepts: order A items, 10 times year; B items, 5 times year; and C items, 3 times year.

A	200	\$500,000	2000	\$250.00	\$25,000
B	300	60,000	1500	40.00	6,000
C	1200	27,000	3600	7.50	4,500
	1700	\$587,000	7100		\$35,500

Results:

Number of line item orders reduced 30%

Average inventory value reduced 27%

* Average inventory value = item count \times order value \times 0.5

2 to 5 weeks	A and B	0.40
	C	0.60
Less than 2 weeks	A and B	0.30
	C	0.50

Average weekly use = annual usage quantity \div 52

Average daily use = annual usage quantity \div number of operating days/yr

Lead time use = lead time \times average weekly usage

Reorder Point

ROP = safety stock quantity + lead time usage quantity

Reorder Point (ROP) is set at usage over the lead time plus safety stock. Thus, for an A item with a lead time of 3 weeks, and an average weekly usage of 12 units, the reorder point would be 50 units, a safety stock of 14 plus lead time use of 36.

Technical Review: The object of this program is to defer, reduce, or cancel reorders for high unit price, and selected A items. Actual quantity requirements are determined by reviewing maintenance and operating plans. Consistent ap-

plication of this concept will result in significant deferral, or cancellation, of cash outlays and will reduce inventory levels.

Since it is impractical to review all reorders, the Technical Review Program requires a detailed review of the reorders that cover the most important reorder decisions affecting materials and purchases; are for items of a high unit price; or are for items designated as critical.

Overstocked Item Analysis: An inventory item with a current balance of more than the safety stock plus one EOQ is considered to be overstocked. The following action should be taken to reduce overstocks:

1. Review quantity on-order to determine if it should be reduced, cancelled, or deferred.
2. Reduce order point and EOQ to reflect current or projected usage trend.
3. Use overstock as a substitute for another inventory item.
4. Initiate disposal or return-to-vendor action.

Overcommitted Item Analysis: An overcommitted inventory item is one having an on-hand and on-order quantity in excess of the sum of the reorder point quantity and one

Fig. 3. Economic order quantity. Annual cost of carrying stock vs. annual cost of ordering under varying order quantity.

economic order quantity. The following action should be taken to reduce overcommitted items:

1. Cancel outstanding purchase order quantities to reduce the on-order quantity.
2. Defer delivery of the on-order quantity until the stock on hand level returns to normal.
3. Review the usage and lead time projections and assure that order point and order quantity are consistent with the current operating plan.

A Item Control Program: A items tie up the majority of inventory investment and represent 70 to 90% of dollars spent on materials and spare parts. Inventory and cost reduction benefits can be realized by carrying out an organized analytical program for each item in the A category. The following are recommended:

1. Competitive bidding should be used effectively and consistently to reduce prices.
2. Annual or longer contracts should be negotiated with scheduled deliveries to minimize stock levels.
3. Salvage and reuse of items should be investigated.
4. Usage rate should be analyzed to determine if redesign, quality control, or improved operating or maintenance practices will lower the usage rate.

Low Value Program: Frequently used fastener products, fittings, small electrical terminals, grease zerks, pipe products, and low unit price items commonly used in an area should be stored in open bins near maintenance work stations. Backup stock for low value items should not be carried in inventory.

The following are characteristics of low value items:

1. Consumables and common hardware items with a low unit value.
2. Specialized items used in one area.
3. Not subject to pilferage or higher dollar loss.
4. Available from local suppliers.
5. Lead time less than 14 days.

A low value overhead account should be used to track costs to each low value station. Warehouse employees should inspect bin areas for low balances and replenish them. Maintenance employees are assigned housekeeping duties.

Inactive Item Management Program

The amount of capital misappropriated to inactive spare parts and operating supplies will vary in mining operations. Often, the investment in inactive items represents between 25 and 45% of the total inventory investment.

The following inactive item control program should be used to manage the inactive portion of the inventory investment:

Inactive Item Review—The inactive items should be sorted into the X, Y, and Z classes, by category, where used, and reviewed annually.

The inventory management department should obtain information on the item or category of items, i.e., purchase order number, date added to inventory, approved by and issue history, and request assistance from operation and maintenance department employees in determining the current status of the items.

The following status categories should be used:

1. **Obsolete**—The item is no longer required.
2. **Critical or Insurance**—The item must be kept in inventory to reduce the risk of curtailing or stopping a major portion of the production flow. Manager or supervisor level approval should be required for this classification. A critical/insurance item code and cost center account number, where used, should be added to the item's record.

3. **Inactive—Retain in Inventory**—Maintenance department employees may be uncertain as to the immediate need for an inactive item. Research may be required to define the item's status. Management authorization should be required to retain an inactive item in the inventory mix and the retention time period clearly defined. A followup review should be performed after three months. If the item's status has not been determined, either return to vendor, sale, or disposal action should be started.

The inactive item investment must be controlled and monitored to reduce capital requirements for spare parts and materials. It is an area where new capital can be recovered from nonproductive assets. Maintenance and operating employees must realize that it costs the average mining company 30 to 35% of the item's value to keep it in inventory. Employees must realize that with sound planning programs, items can be ordered and delivered, just-in-time for their needs.

Inventory Investment Controls

New Stock Item Budget—A new stock item budget and management controls will help regulate inventory investment increases. Each year, materials management, operations, and maintenance department supervisors analyze the current mine plan, the approved capital appropriation budget, and the maintenance department's major maintenance and rebuild plans, and subsequently, project new requirements for the inventory. A budget is prepared for each mine process and the maintenance department and submitted for approval by the mine manager.

Requests for additions to the inventory mix should be submitted on new item requisitions and approved by the department manager. Once a department is over budget on new item additions, senior management approvals should be required for the request.

Monthly, materials management should prepare a report on the new item additions, comparing budget and actual dollar amounts for the current period and year-to-date.

Verifying Investment Value and Quantity Levels—Accurate quantity and value levels are important for the financial, materials management, operations, and maintenance departments. Checking a record to confirm an on-hand balance and then finding the bin empty creates maintenance and operation scheduling problems and financial reporting errors. In addition, reordering an item before its balance reaches the reorder point level may create an overstock situation; reordering at a level lower than the reorder point increases the risk of stock-out.

Record accuracy checks and financial record verification should be an ongoing procedure. A cycle counting policy and schedule works well in the mining industry.

The cycle counting program should include a more frequent count schedule for high usage value items (A items), critical items, and items with frequent count errors. The following schedule is recommended:

Item Class or Status	Count Frequency
A, critical, and frequent count error items	Quarterly
B and high unit price items	Semiannual
C and new stock items	Annually
Inactive items	Every two years

Inventory record checks can also be performed when an item is at a zero balance level. The warehouse clerk flags the issue requisition as having a zero balance and the inventory control clerk compares the physical and record balances. If a discrepancy exists, the clerk adjusts the record or requests a second count. (Expediting action should be initiated if the item is on order and the item's scheduled count date adjusted.)

A management report should be prepared on cycle counting activities. The report could include:

1. The number of items counted this month and year-to-date.
2. The value of adjustments (debit and credit) for the current period and year-to-date.
3. The number of items to be counted the next period and for the year.
4. Highlights on adjustments and problems.
5. Performance statistics (the number of counts per employee per day, etc.).

Items with frequent count errors should be evaluated and controls improved. The following controls may reduce count errors: (1) improved warehouse security; (2) locked storage cabinets; (3) issued by supervisor only; (4) controlled access to warehouse storage areas.

Active Item Budget—A budget should be prepared annually for the active investment. The active item budget should include financial requirements for each category based on the mine production and processing plans; the Maintenance Department's schedule for planned maintenance and major overhaul activities; and an analysis of past performance and future requirements when parameters are changed. An active item simulation program (Fig. 4) could be used to define future needs based on changes in market and mine conditions or the system's reorder decision rules. The budget should be adjusted monthly for changes in production and maintenance plans, usage, lead time, and unit price changes.

Inactive Item Reduction Goal—A goal should be prepared annually for reducing the amount of capital misappropriated to slow moving and no longer needed spare parts and material. The goal should be prepared based on a review of inactive item classes, a profile of the inactive item investment (Fig. 5), past performance, and a review of the production and maintenance plan and equipment utilization estimates. The goal should include monthly capital reduction estimates by material category and it should be adjusted for mine and market condition changes.

PURCHASING

Introduction

The Purchasing Department plays an important role in a mining venture. They must wisely and safely spend millions of dollars for material, spare parts, equipment, services, and equipment leases. In spending the operating capital, they must insure that the vendor can perform the service or deliver the requested material at a competitive price, on time, and as requested. Mishandling a purchase order could result in lost revenues, downtime, and idle labor.

In addition to its purchasing function, the department should have responsibility for the sale of obsolete items, returning material to vendors, contract and blanket order negotiations, vendor selection, expediting, routing of incoming material, evaluating vendor performance, and adjusting purchase order commitments for changes in operating plans and market conditions.

The following programs are recommended:

Quotation Policy

The department should request price and delivery quotations for multiple source items when a requisition exceeds \$2000. Quotation replies should be analyzed and reviewed with the requesting department managers for nonstock requisitions, capital item purchases, and service and performance contracts. The department should use good business judgment in determining if a quotation should be requested for requisitions under \$2000.

Expediting Policy

Expediting action should be initiated for late delivery items, inventory items with a low or zero balance on hand, and items that require improved delivery dates and priority code AA purchase orders.

The department should contact the vendor and request status information on the scheduled shipping date, route of shipment, transportation agent, and bill of lading number.

New or revised delivery date information should be conveyed to the requisitioning department so they can update their schedule and plan the work or project.

Trial of Commodity and Value Analysis Programs

For stock items and commonly used direct purchase items, standard brand and vendors should be established. A program to evaluate the use of different brands or vendors or substitute items by performing a trial of the new item is called a *trial of commodity* program.

A trial of commodity may be initiated by Maintenance, Operations, or Purchasing. A trial of commodity form is completed and a copy attached to a purchase requisition for the material to be tried. The user is responsible for executing the trial and reporting on the results. If, as a result of a trial, a new item is selected as a substitute item, the order description and vendor's record should be updated.

In the value analysis program, spare parts and materials are evaluated for price, wear life, cost, and end use application. The analysis includes a determination of ultimate cost per unit of production or operating hour, maintenance cost for part replacement, and the cost of carrying the inventory of spare parts. Financial results are reviewed and approved by management before the new product or spare part is approved for purchase.

Priority Requisition Processing and Procedures

A priority requisition processing policy and procedure is needed to define priority codes and conditions, control rush and emergency requisitions, establish procedures for processing priority requisitions, and to define approval level required for priority codes.

Priority codes are assigned to requisitions according to the severity and effect on production or cost. A service delay or production loss caused by lack of an item should justify priority handling and air or special transportation.

Four codes and processing conditions should be assigned. They are:

Code	Situation	Processing Requirement
AA	Critical	Immediate
A	Important	Within two hours
B	Urgent	Day after requisition received
C	When requested	Within two days

For critical and important condition (AA and A codes) the department manager or vice president should be notified

Notes

Line 1. Includes item status information on the inactive item (see active item simulation legend for abbreviations).

Line 2. LST ISS DTE = date last issued; LST ISS Qty = quantity last issue; MTH LST ISS = number of months since last issue; TOD = date added to file; shelf life = shelf life for item; expected stock-out date = estimate date stock on hand will be at a zero balance.

Summary. Total number and value of inactive items and value and percentages for safety stock, strategic, and insurance items.

Recap. A profile of inactive stocks (number, value and percent of total) by last issue date.

and he should approve the coding. The conditions for critical and important situations are:

1. *Critical*—Department production goals or operating objectives are affected and cannot be made up.

2. *Important*—Department production goals or operating objectives are affected but can be made up at additional cost.

Evaluating Quantity Discounts

Maintaining stable prices or reducing unit prices in an inflationary environment requires that buyers search the market for price, quality, and availability. It also requires that the buyer evaluate the cost of carrying an increased quantity in stock if a larger quantity is purchased. A quantity discount evaluation form (Fig. 6) should be prepared before the larger quantity is purchased. The cost savings from a lower purchase price must be greater than the cost of carrying a larger quantity in inventory.

Source of Supply/Spare Part Cross-Reference Program

Single purchase source spare parts and materials offer opportunities for unit price reductions and lower material and spare part costs. Product cross-reference information is available from many fastener, oil filter, bearing, seal, and V-belt vendors.

In addition to vendor cross-reference catalogues, warehouse employees can obtain spare part source information

from labels or identification tags attached to the spare part or from maintenance employees.

Purchasing original equipment spare parts from alternate vendors generally reduces unit prices between 30 to 60%. Product specification information, including mounting position, amp, volts, psi pressures, dimensions, and product hardness, etc., must be provided to alternative vendors. Product warranty and maintenance compatibility information should be obtained before committing future requirements to the new source.

Contracts and Blanket Orders

Contracts and blanket orders should be negotiated for the purchase of major operating supplies, essential spare parts, high usage dollar products, and frequent purchase materials. Simplified order release and scheduled delivery date techniques should be used to order and release material.

Negotiating favorable contract terms will reduce or stabilize material and supply costs and provide an assured source of supply. The following terms and conditions should be negotiated:

1. Price.
2. Invoice payment.
3. Product warranty.
4. Backup stocking.
5. Product returns.
6. Cancellation.

Quantity Ordered: _____ Notified: _____

Purchasing Comments: Scheduled 400 for delivery on 1/27/83; 200 on 2/18/83; 200 on 3/1/83 and 200 on 3/17/83. Advised to ship via Fast Freight prepaid.

BUYER: James Price

7. Contract extension.
8. Quantity discounts for noncontract items.
9. Vendor services, etc.

Surplus and Obsolete Item Disposal

Material, spare parts, and equipment that will no longer be required because of a change in the mine plan or production goal should be sold or transferred to other properties. The sale of nonproductive assets will improve the company's cash position. When the mine's operating plan changes, or when the production goal has been decreased, the purchasing department must review its order commitments and stock levels. Purchase order cancellation, delivery date deferrals, or return to vendor action should be started immediately.

INFORMATION PROCESSING

Large volumes of transactions are prepared and processed by the purchasing, inventory management, and warehousing departments. Records must be retained for thousands of items. They must include accurate and timely information on an item's status, description, value on hand, incoming shipments, etc.

In addition to inventory records, Purchasing must retain information on open and outstanding orders, vendors, contracts, prices, receipts, contract expiration dates, purchase order values, and accounting information, etc.

Fast retrieval of accurate information is essential so that managers can make reasonable financial and operating decisions on the amount of operating capital required for the purchase of material and spare parts; on scheduling a major overhaul; on retaining or returning a spare part; on placing an order to replenish stock levels, and decisions on material and spare part costs for a piece of mining equipment, processing plant, or mine area. Purchasing and warehousing must contribute to the data base.

An on-line computer system that interacts with accounting, maintenance, and operations should be used for purchasing, inventory management, and warehousing. The design of the system must respond to the needs of users, the operating environment of the property, and must support the objectives of materials management. These objectives should include:

1. A specific level of support to the operation minimizing total ordering and inventory carrying costs.
2. Efficient purchase order releasing and order status reporting.

3. Highlighting problems through exception and summary reporting.
4. Providing appropriate vendor and buyer evaluations.
5. Reducing routing clerical activities.
6. Timely input and processing of system information.
7. Predicting spare part and material requirements accurately, using current operating and maintenance plans and historical usage information.
8. Minimizing the capital required for inventory investment.

CRT screens should be located in work areas in the purchasing, inventory management, and warehousing departments. The screens should be used to inquire on file information and for data entry. CRT screen displays should include a screen menu on files that can be accessed and self-help messages for data entry. The terminals should have controls for accessing file information, updating files, and data entry. Sign-on and password controls are also necessary for system security.

The following reports or screen displays are recommended:

1. *Status Reports*—provide historical and current information on inventory items and purchase orders.
2. *Exception Reports*—provide historical and current information on items or conditions outside of normal operating parameters.
3. *Performance Reports*—provide information on operating conditions and dollar levels.
4. *Summary Reports*—highlight material activities, i.e., investment levels by category, item class and location, by property, process and storage area.
5. *On-Request Reports*—one-time or infrequent use reports on special situations or conditions. The report should provide information on a single item or group of items.

The system must be capable of responding to changes in operating plans, maintenance schedules, and market conditions.

MATERIALS MANAGEMENT SUMMARY REPORT

The materials management summary report, Fig. 7, should measure department performance relative to goals or objectives and provide status information on inventory management, purchasing and warehousing activities, and manpower. The report should include current month, prior month, and year-to-date information, performance and goal statistics, and variance analysis. Detailed reports should provide backup information.

8.9 Government and Public Affairs

CHARLES S. BURNS

Over the years a mining company's relations with government, particularly the federal government, have become increasingly important to the point that they are now a vital management function.

Based in Washington, D. C., the American Mining Congress is the national trade association which represents before the federal government the producers of most of America's metals, industrial and agricultural minerals; manufacturers of mining and mineral processing machinery, equipment and supplies; and engineering and consulting firms and financial institutions that serve the mining industry. Together with the National Coal Association, it also represents the coal industry. In 1963, the AMC had a staff of 14 professionals and 24 support personnel for a total of 38 employees. Twenty years later, in 1983, its staff had grown to a total of 90, including 47 professionals and 43 secretarial and clerical employees.

The major steel companies, which have captive coal operations, have long maintained their own government affairs offices in Washington. However, with the exception of the steel industry, in 1963 there was only one independent coal company with a Washington office. In 1983 there were at least ten such offices. Only one copper mining company had a Washington office in 1963. Twenty years later almost every major company has Washington representation.

Why has the mining industry dramatically expanded its presence in Washington over the last twenty years? The answer can best be given in a recitation of federal government actions. In 1963 there was:

1. No *Federal Metal and Nonmetallic Mine Safety Act* (enacted in 1966 and incorporated with the Coal Safety Act into one statute in 1977).
2. No *Wilderness Preservation Act* (a wilderness system composed of 9.2 million acres was enacted in 1964).
3. No *Solid Waste Disposal Act* (enacted in 1966).
4. No *Resource Conservation and Recovery Act* (federal and state controls over hazardous wastes were enacted in 1976).
5. No *Wild and Scenic River System* (enacted in 1968).
6. No strong federal *Water Pollution Control Act* (federal guidelines for states to require pollution controls enacted in 1972).
7. No stringent *Clean Air Act* (legislation establishing national ambient air standards for pollutants enacted in 1970).
8. No *National Environmental Policy Act* (1970).
9. No *Alaska Native Claims Act* (1971).
10. No *Alaska National Interest Lands Conservation Act* (1980).
11. No *Noise Control Act* (1972).
12. No *Endangered Species Act* (1973).
13. No *Safe Drinking Water Act* (1974).
14. No *Toxic Substances Control Act* (1976).
15. No *Federal Land Management and Policy Act* (1976).
16. No *National Forest Management Act* (1976).
17. No *Surface Mining Control and Reclamation Act* (1977).
18. No *Uranium Mill Tailings Radiation Control Act* (1978).

This is only a partial listing of federal statutes that have affected mineral exploration, development, and production. And, of course, with each federal statute there comes a federal regulatory scheme.

What has happened in twenty years to so change the landscape? In the early 1960s the mining industry's principal concerns on the federal level were taxation, the management of government stockpiles of strategic minerals, and access to the public lands for prospecting for and mining of mineral resources. The pertinent committees of Congress concerned with public land management and mining interests generally were the House and Senate Interior committees (the latter is now known as the Committee on Energy and Natural Resources).

These committees were dominated, if not controlled, by members of Congress from the Western states who understood the problems of the mining industry and who, in large part, sought to encourage mineral development. Twenty years later these committees, though still containing Western members, have been deliberately filled with members from other parts of the country who represent a strong environmental bias and are, in many cases, openly hostile to mining.

The major cause of these changes in the Washington political landscape is, of course, the emergence of the environmental movement as a powerful political force. In the early sixties, the leaders of the old line, respected conservationist organizations sought federal legislation to impose environmental requirements on mineral development designed to protect the environment while, at the same time, permit mining to continue. By the early 1970s, however, the environmental movement had been radicalized. At most of the environmental organizations, positions of staff leadership were assumed by ultraleft professional activists. Expanding their efforts beyond Congress to the courts and, during the Carter Administration, to the Executive Branch itself, these militants sought not just to control mining, but to prohibit it. Exploiting legitimate environmental concerns as a means to their end, they have sought to establish a no-growth policy for the nation in an effort to change fundamentally the nation's economic system.

Clearly a mining company attempting to operate in such a climate cannot long succeed without devoting major attention to government relations and public affairs. That is the reason for the growing number of mining representatives in Washington.

USE OF TRADE ASSOCIATIONS

Companies maintaining Washington offices make extensive use of their industry trade association as well as the general business associations such as the Chamber of Commerce of the United States and the National Association of Manufacturers. Certainly companies without Washington representation should look to their association for help.

Such help is a two-way street and a company must be willing to devote expertise and man-hours to the enterprise. For example, the American Mining Congress has 29 standing committees and numerous subcommittees, their membership drawn from the ranks of its member companies. Each year

a company is asked to recommend individuals to serve on one or more of these committees. Although the AMC staff guides the work of the committees and performs a secretariat role, policy is molded and substantive work is done by the members themselves. A list of the standing committees reflects the myriad of problems and issues emanating from actions taken or considered by the federal government:

- Accounting
- Capital Formation
- Cement Advisory Council
- Coal Leasing
- Coal Mine Safety
- Coal Policy Council
- Coal Preparation and
Waste Disposal
- Coal Surface Mining
- Communications
- Diesel
- Energy Resources Policy
- Environmental Matters
- Export Council
- Financial Advisory Council
- Industrial Relations
- Manufacturer Technical
- Minerals Availability
- Mining and Minerals
Education
- Noncoal Mine Safety
- Noncoal Surface Mining
- Occupational Health
- Product Liability
- Public Lands
- Reclamation Technology
- Silver
- Synthetic Fuels
- Tax
- Undersea Minerals
Resources
- Uranium

Clearly a company cannot have representation on every committee. However, it should attempt to obtain membership on those committees dealing with issues which are of prime importance to it or, at the very least, be placed on the mailing list to receive information.

Specialists should be chosen to serve on committees that require technical expertise, such as, tax, mine safety, or reclamation technology. Otherwise, it is usually best to place a generalist in charge of coordinating the company's overall government relations activities.

Mining companies also should maintain membership in the national associations that represent business in general, such as the US Chamber of Commerce and the National Association of Manufacturers. Both of these organizations have Natural Resources committees composed of representatives of member companies. In testimony before Congress and in policy statements directed to the Executive Branch and the public, their positions are generally similar to those of the mining associations, but they bring to those positions support from a broader national constituency.

State mining associations have been established in most states in which surface mining is conducted. These state associations monitor state legislative and administrative developments that impact upon the industry and assist the national associations in their efforts on the federal level. State associations generally have small staffs (usually a director,

sometimes called a *secretary*, with one or two assistants). In order for them to be effective, corporate participation is essential.

THE VALUE AND FUNCTION OF A WASHINGTON OFFICE

Despite their efforts on a variety of issues, trade associations can only assist the industry in collective endeavors. As a result there are many times when a company requires its own Washington representation. Frequently, a company will have a problem with the federal government that is uniquely its own, whether it be negotiation of a lease or a regulatory or legislative issue that is site specific. Policy differences in a particular segment of the industry may prevent the trade association from achieving a consensus and thus participating in the effort. For example, the uranium industry was divided over legislation to impose restrictions on the importation of foreign uranium. Domestic producers favored it. US companies with extensive foreign production opposed it. As a result, the Mining Congress could not take a position on the subject.

Although there are some exceptions, most corporate Washington offices are small, consisting of one or two government relations specialists and support staff. In general, public relations staff is maintained at corporate headquarters.

It is the responsibility of the Washington representative to monitor those activities of the federal government that have a direct impact upon the company and report such developments to senior management. The Washington representative must present policy positions of the company to members of Congress and their staffs and officials of the Executive Branch. In doing this, the representative is frequently accompanied by company personnel who are specialists on the particular issue being discussed.

The Washington representative's *box* on the table of organization varies from company to company. Sometimes it is a function falling under the purview of the general counsel. In other companies the Washington representative reports to a senior vice president for corporate and legal affairs, or, in rare instances, directly to the chairman or president.

The exact positioning in the chain of command is not important as long as the Washington representative has ready access to the highest policy-making levels of the company. Many times a corporate policy decision on an impending government action must be made swiftly and such decisions may be influenced by political facts and nuances that can be inadvertently misstated if reported through intermediate parties. That is why it is vital for the Washington representative to have direct access to those in the company who must make the decision.

GRASSROOTS NETWORK

Most companies with Washington offices have established *constituency building* or *grassroots lobbying* programs which are developed and implemented by the Washington office. The purpose of such a program is to facilitate and supplement corporate activities designed to influence public policy through both the electoral and legislative processes.

Once established, such a program can become remarkably effective. For example, one company with facilities located in 15 states appoints an employee at each location to be the *Government Affairs Executive* for that area. Such an assignment is in addition to his regular duties. The executive (known as a GAE) is expected to become personally acquainted with the congressman representing his district and

the two US senators from that state. Plant tours by these officials are encouraged.

The Washington office, through publication of a newsletter and other communications, keeps the network of GAEs informed of federal issues of importance to the company. At the appropriate time, the GAEs are asked to contact their assigned members of Congress (by letter, telegram, or, if urgent enough, by telephone) expressing the company position on a given issue. Once each year all the GAEs are brought to Washington for several days of meetings, briefings, and visits with their senators and congressmen on Capitol Hill.

The value of such a program is considerable. It is one thing for the Washington representative (or the chairman, for that matter) of a company operating in a congressman's district to contact him on a legislative issue. It is quite another thing—and far more meaningful—for that contact to be made by the plant manager who works, lives, and *votes* in the congressman's district.

POLITICAL ACTION COMMITTEES

Recent years have seen a steady rise in the number of companies which have formed political action committees. Such committees have been utilized by labor unions and other special interest groups for decades. A change in federal law in 1974 clarified a corporation's legal right to operate such a committee, known as a PAC.

The PAC permits employees to pool their individual

political contributions and thereby render meaningful support to candidates for Congress who recognize the problems of industry and who will work to establish an economic climate that is conducive to business growth. Employees are solicited by the PAC, generally by letter, and this is followed by discussion of the program at informal employee meetings. Employee contributions to the PAC are voluntary and strictly confidential.

Many PACs are managed by the firm's Washington representative who either sits on the committee that decides which candidates will receive contributions or serves as an advisor to the committee.

PUBLIC RELATIONS

The management of corporate relations with the media, the public, and the shareholders is a function best kept separate from government relations. For obvious reasons, the company lobbyist is not the ideal spokesman to explain a plant closing to the press and public nor should he be exposed to questions on legitimate, but perhaps delicate, negotiations being held with legislators or other government officials.

Nevertheless the roles are somewhat similar and are best supervised by an officer in charge of corporate, legal, and public affairs. Volumes have been written on effective public relations techniques and such information will not be repeated here. Suffice it to say that honesty and accessibility—a willingness on the part of company leaders to meet the press and public—are the overriding principles to follow.

CHAPTER 9

Case Studies

Bruce A. Kennedy, Editor

1. Introduction

BRUCE A. KENNEDY

The first eight chapters of this book have dealt with the details of the numerous and diverse parts of surface mining. In the case of a mining project, all these components must be pulled together to result in an efficient and profitable operation. Each mining project is unique and consequently the final form of the eventual operation will be influenced by many factors. These will include, but certainly not be limited to, commodity, geographic location, geology, environmental considerations, scale, available labor skills, capital and operating costs, etc., etc.

This chapter contains seven case histories of open pit mining different commodities in various locations in the world. The mines examined are Hambach, West Germany—coal; Palabora, South Africa—copper; Metcalf/Morenci, USA—copper; Cuajone, Peru—copper; Chuquicamata, Chile—copper; Shirley Basin area, USA—uranium; and Island Copper, Canada—copper. The only criterion in the selection of these particular mining operations was to demonstrate the wide diversity of situations and problems that can be encountered in surface mining and the solutions that can be found to deal with them.

9.2. The Hambach Open Pit Mine

DIETER HENNING
HANS WEISE

INTRODUCTION

The Federal Republic of Germany has a total of some 56 Gt (62 billion st) of lignite resources, of which approximately 55 Gt (61 billion st) are contained within a triangular area bounded by the cities of Cologne, Aachen, and Dusseldorf (Fig. 1). Based on today's energy prices, about 35 Gt (39 billion st) of this total is economically minable. This so-called Rhenish mining area (*Rheinisches Revier*) thus contains Europe's largest continuous lignite deposits.

Presently, Rheinische Braunkohlenwerke AG (Rheinbraun), Cologne, is operating five open pit mines in the Rhenish mining area: Frimmersdorf, Fortuna-Garsdorf, Frechen, Ville, and Zukunft. The combined lignite production from these mines approaches 120 Mt/a (132 million stpy). With the exception of the Frimmersdorf mine, reserves in all mines will have been exhausted by the early 1990s.

The output of mine extensions and/or new developments (at Inden, Bergheim, and Hambach) will serve to maintain present production levels. Beyond the year 2000, however, three large-scale open pit mines will still be in operation, with lignite production as follows:

Frimmersdorf/Garzweiler 45 to 50 Mt/a (50 to 55 million stpy)
Hambach 45 to 50 Mt/a (50 to 55 million stpy)
Inden 20 to 25 Mt/a (22 to 28 million stpy)

THE HAMBACH MINING AREA: HYDROLOGY AND DEVELOPMENT HISTORY

The Hambach deposit, which was initially explored in the 1940s, is located in the so-called Erft block, situated near the geographic center of the Rhenish mining area. This 85-sq-km (33 sq-mile) area (Fig. 2) holds lignite reserves of some 2.5 Gt (2.8 billion st), the mining of which involves removal of 15.4 km³ (20 billion yd³) of overburden, yielding an overall stripping ratio of 6.2:1 m³/t (199 ft³/st).

The western boundary of the deposit is formed by the so-called *Rur peripheral fault* (Fig. 3). Here, the seams split up initially into six segments, which dip 3 to 4% to the northeast. In the southeastern area of the mining field, the seams coalesce into a continuous unit with a thickness of up to 70 m (230 ft). In the remaining sections, the individual seams are separated by interburden of varying thicknesses. The lignite has a mean heating value of 9800 kJ/kg (4213 Btu/lb), with an average water content of 50% and ash content of about 7%.

The rock overlying the lignite seams has a thickness varying between approximately 150 m (492 ft) in the west and 400 m (1312 ft) in the east. The overburden, like the intermediate rock, consists of nonindurated sediments: 70% sand and gravel, 30% cohesive clays and silts. Unlike other deep open pit mines presently in operation in the Rhineland, this mine is traversed from the southeast to the northwest by only a few small faults, with vertical displacements seldom more than 15 m (50 ft).

Due to the presence of several large interbedded aquifers,

it is nearly impossible to mine the deep seams of the Hambach mine without first providing extensive dewatering. Satisfactory in-pit working conditions are assured only by proper ground water collection procedures (Leuschner, 1972).

From the hydrological point of view, the Erft Basin, developed for the first time by the Hambach mine, is to a great extent shielded against adjacent water-bearing areas by the existing fault system. Thus, the lowering of the ground water table for the Hambach mine will mainly be confined to the Erft Basin, which covers some 850 sq km (328 sq miles). Additional relief is provided by the Erft Basin drainage system, which has been in operation for more than two decades. This drainage system was initially constructed to insure sufficient stability for slopes in neighboring mines which extended into the Erft Basin.

In the next few years, the quantity of ground water raised from the Erft Basin will need to be increased only slightly and should decline in the late 1980s. When the mine reserves are exhausted, another 100 dewatering wells will have been drilled in the mining field at its rim to be added to the present array of 260 filter wells being operated in the Erft Basin.

The pump wells reach depths of 520 m (1706 ft); the water is raised by submersible pumps with capacities of 15 to 30 m³/min (530 to 1060 ft³/min). These quantities are either discharged into natural water courses or are collected to meet the demand of local public and industrial users. So far, lowering the ground water level has caused only limited damage to wild and cultivated plant life since the fertile loess and forest soils covering the surface have a high water storage capacity, allowing plants to meet their water needs from precipitation.

The lignite deposits in the area of Erft Basin are minable beyond the boundaries now fixed for the Hambach mine; however, primarily population density and landscape planning criteria have defined the boundaries of the mining area and its division into Hambach I and Hambach II (Fig. 2). The long-term planning scheme provides, first of all, for the Hambach I field to be worked leaving the decision on Hambach II to be taken in the mid-1990s. Extensions going beyond these boundaries in the next century are quite conceivable, if necessitated by future energy requirements.

The mine plan selection process for the Hambach deposit involved studies of more than 20 variants in an attempt to satisfy two basic criteria: the smallest possible outside dump volumes, and an expeditious startup schedule (Leuschner, 1972). The selected mine plan incorporated a slewing operation with a bench length of approximately 5 km (3.1 miles) and the slewing point located in the southwestern part of the field. With a clockwise slewing pattern, the overall deposit can be mined from one slew point with a nearly constant bench length (Fig. 2).

In 1978 development work started in the flattest part of the mining field with a box cut in parallel operations. Due to its length [some 5 km (3.1 miles)], this box cut was not excavated separately, but widened by the first bucket wheel excavators and gradually deepened. Lignite was reached and mined for the first time in 1983. By then the cut will be approximately 5 km (3.1 miles) long, 1.8 km (1.2 miles) wide

The following concept was worked out to handle the outside dump volume of 2.7 km³ (3.5 billion yd³). In the first five years, the overburden volumes were disposed of solely in the *Sophienhoehe* outside dump, located northwest of the box cut. The *Sophienhoehe* will eventually be comprised of nearly 1 km³ (1.3 billion yd³) of overburden. The site chosen has the advantage that the *Sophienhoehe* can later be continued directly to the future inner dump. Another 1.7 km³ (2.2 billion yd³) of outside dump volumes will be transported to the Fortuna-Garsdorf, Frechen, and Bergheim mines to fill the final mine voids. Two conveyors, some 14 km (8.7 miles) in length each, will move more than 0.10 km³ (130 million yd³) of overburden volume per year from Hambach to these mines (Fig. 4).

To build up the first inside dump, the first spreader will transport overburden from the *Sophienhoehe* to the mine. Via a ramp system, the three dumping benches will alternately be worked with two equipment systems (Fig. 5). By that time, a volume of nearly 0.80 km³ (1046 million yd³) of outer dump material will have been moved. Late in 1990, the *Sophienhoehe* outer dump will be completed. The mine will attain its full operating capacity of 50 Mt/a (55 million stpy) in the mid-1990s, with eight excavators planned for operation during the final stages (Fig. 5c).

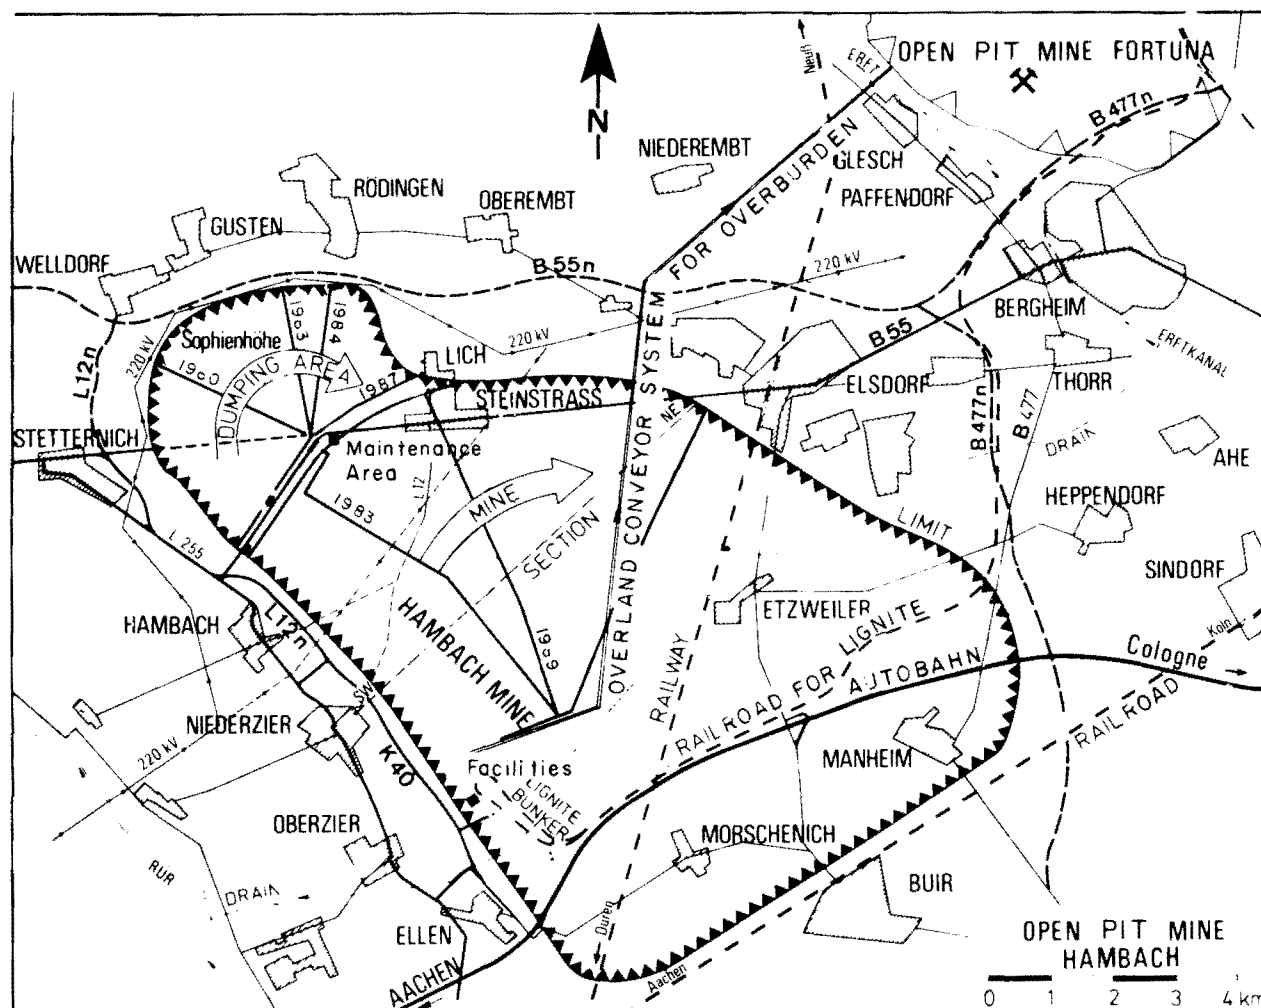

Fig. 2. Area of the Hambach deposit.

As presently planned, the Hambach I mine will be exhausted by about 2040. Should a decision be made on Hambach II or on mining the large lignite reserves beyond the southern boundary, higher output will be possible by employing additional equipment groups without any change in basic operating concepts.

RECLAMATION AND POPULATION RESETTLEMENT

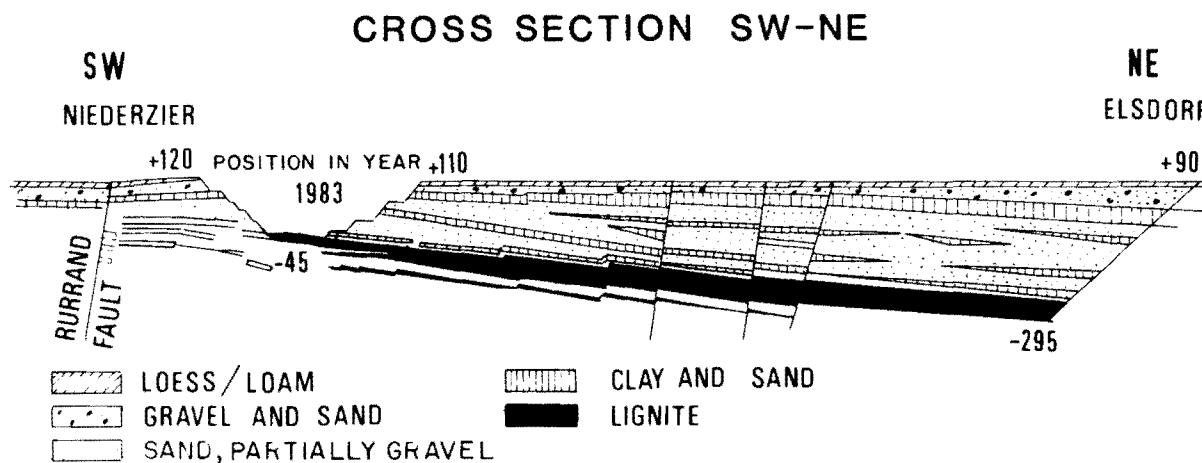

The Hambach mining area consists mainly of farmland (48%) and forest (47%). To replace the large wooded area disturbed by mining operations, the *Sophienhöhe* outer dump is to be reclaimed as forest, thus providing a quiet recreation area. Planning for the high dump, therefore, necessitates special monitoring of the continuously updated landscaping data. By mid-1982 some 230 hectares (568 acres) had been reclaimed on the peripheral slopes and on the plateau, with some areas opened to the public (Fig. 6).

Filling the final voids at the Fortuna, Frechen, and Berghheim mines will produce 2600 hectares (6425 acres) of reclaimed land, mostly agricultural. In total, 3800 hectares (9390 acres) in the Hambach area will be restored for forestry, and 1000 hectares (2471 acres) for agricultural purposes.

This will leave 3700 hectares (9143 acres) in the southern portion of the present mining area to be filled with outer dump volumes from mine extensions, part of which will possibly be laid out as residual lakes.

Compared with the population density of the Rhenish area [420 persons per sq km (0.39 sq mile)], the population density in the Hambach lignite field [about 60 persons per sq km (0.39 sq mile)] is very low. In addition to some farms that were already acquired in the initial phase or that are presently being resettled, only the township of Lich-Steinstrass will be relocated to Juelich. This relocation will be carried out in accordance with the wishes of the inhabitants, and will be completed by the year 2000 (Figs. 2 and 7). The last community to be reached by mining operations (in about 50 years) will be Morschenich.

As a part of mine development at Hambach, substitute roads were constructed for Highway L12 between Steinstrass and Niederzier and for a section of Federal Highway 55 (Fig. 2). Thus, the connecting road between Federal Highway B55 and Highway L12, the so-called *mine road* open to public transport, branches off between the mine and the Sophienhöhe. A 200 m (656 ft) section of the road runs through a tunnel over which the conveyors to the outer dump are

routed. The final substitute road for Highway B55 will be built on the northern rim of the Sophienhöhe in the late 1980s.

After the year 2000 a section of Autobahn A4 and the federal railroad line from Dueren to Neuss will have to be relocated parallel to the present railroad line from Cologne to Aachen, in addition to other sections of federal and state highways.

EQUIPMENT SELECTION AND SITE PREPARATION

Equipment selection philosophy for the Hambach mine was based on improving technology and increasing machine capacity. These advances were stimulated by the need to offset a portion of the cost increase resulting from mining

under stripping ratios less favorable than those found in other mines in the Rhenish mining area. The design and operational geometry of the excavators and spreaders are comparable to time-tested equipment with a capacity of 110 000 m³/d (143,875 yd³/d). The large-scale equipment and conveyors used at Hambach, however, have a daily capacity of 240 000 m³ (313,908 yd³). Increasing capacity not only requires greater driving power (especially in the area of the bucket wheel and conveying routes) but also involves increased service weights and higher belt speeds (Figs. 8 and 9).

The conveyor systems, consisting of 2800-mm (110-in.) wide belts of ST 4500 quality, have been designed for a belt speed of 7.5 m/s (24.6 ft./s) and driving power of as much as 6×2000 kW. The design and steel construction of the belt conveyor driving stations and supporting structures were based on experience gained with units operating at the For-

tuna mine, but feature two major improvements: (1) the spacing of the three-part garlands of the upper belt was increased from 1.25 m to 1.875 m (4.10 to 6.15 ft), thus reducing the number of garlands per support, from 6 to 4, and (2) the tail stations have been completely redesigned and can be transported by mobile crawlers. The mine's auxiliary systems and vehicles are largely identical in type with those used at other Rheinbraun mines.

In mid-1982, the Hambach mine had an equipment inventory consisting of:

- 20 motor graders, including 5 bulldozers on wheels
- 12 loaders and cleaning vehicles
- 4 pipe layers
- 11 auxiliary excavators and
- 28 other items, such as crawlers, cranes, low-loaders, rolling mill engines, among other equipment,

and a vehicle fleet consisting of

- 45 trucks, personnel carriers, and tractor trucks
- 42 passenger cars and
- 70 trailer wagons.

Power is supplied to the mine via a two-system, 380-kV overhead line by RWE (Rheinisch Westfaelisches Elektrizitaetswerk, West Germany's major electricity supplier) and three 200-MVA transformers that feed 30 kV into the mine's central switchgear plant. The equipment in the mine itself is connected radially to the switchgear. Some 350 km (217 miles) of 30-kV service cables and supply lines for equipment, conveyors, and the drainage system were laid by the end of 1980.

In order to assemble the first three large-scale equipment groups (excavator, spreader, and tripper car), the necessary sites were prepared at the slew point of the Hambach mine late in 1975, with machine assembly commencing in 1976. Machinery components were transported by suppliers to these sites via highway only. Assembly work proceeded on

schedule, with erection of the belt conveyor head and tail stations beginning early in 1978 (Fig. 10).

Starting in early 1977, Hambach's surface installations were built in a large complex near the assembly sites for the large-scale equipment. They included social, operational, and office buildings, workshops, stores, fire house, central control station, central switchgear plant, and numerous facilities for the mine's services and waste disposal systems (Fig. 10). A small base with social and operational buildings as well as a workshop was installed for the work force allocated to the dump site at the slew point of the Sophienhoehe outside dump. Here, too, is the Sophienhoehe belt distribution point where shiftable transfer stations (shunting heads) handle the transfer of material from the excavators to the spreaders (Fig. 11).

In 1976 the first wells draining westward toward the Ruhr river were put into operation near the slew point area of the mine. The drainage system was designed to handle a maximum water quantity of 2 m³/s (71 ft³/s). Early 1978 saw the completion of the first extensive intercepting scheme that routed water eastward to the Erft river. This scheme consisted of an 11-km (6.8-mile) long steel pipe system and the 8-km (5-mile) long Wiebach conduit system. The conduit system is comprised of concrete pipes as much as 2 m (6.6 ft) in diameter and having a maximum flow rate of 6 m³/s (219 ft³/s).

Late in 1980, the second drainage system to the Erft, namely the Finkelbach conduit system in the northeast, started operating, likewise with a capacity of up to 6 m³/s (219 ft³/s). All pipes were laid underground with the disturbed land restored on completion of the work.

In addition to the present 142 deep wells and 13 surface wells [maximum 25 m (82 ft) deep], approximately 290 exploration and 149 piezometric boreholes have been drilled since 1974 to explore and examine the geological, geomechanical, and hydrological conditions of the lignite and overlying strata. Overall, the mining field so far developed has a density of approximately 25 boreholes per sq km (0.39 sq mile).

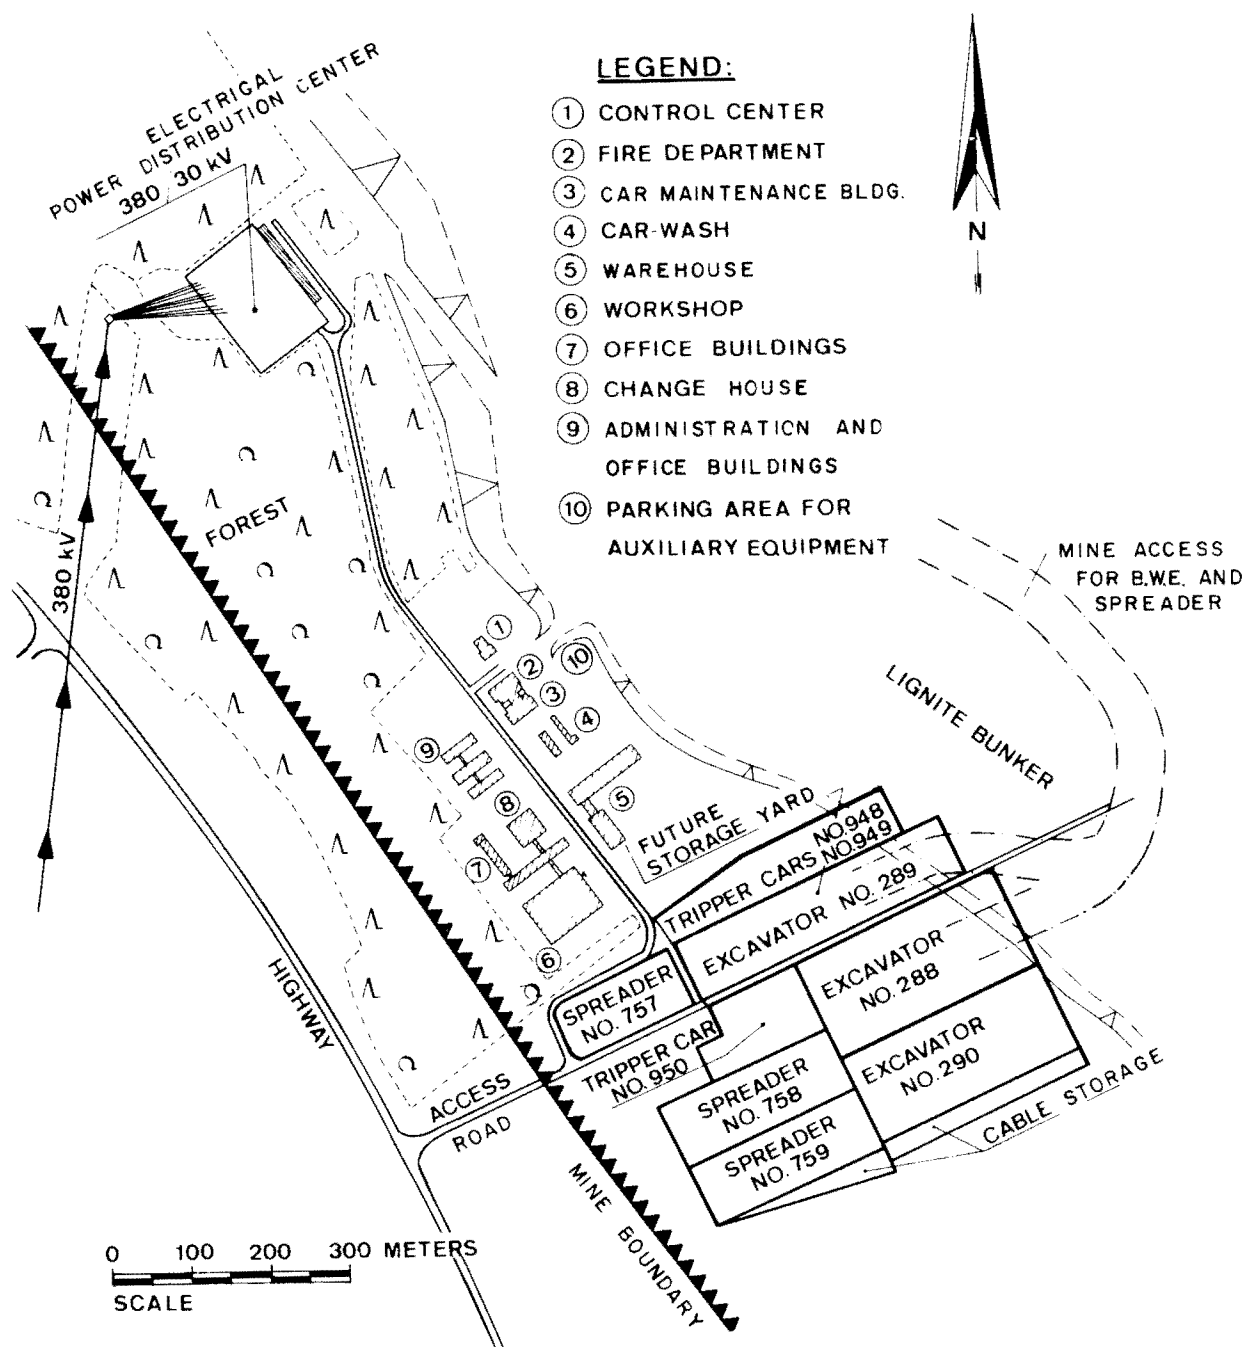

Fig. 10. Site plan of the facilities and erection area in 1978.

In mid-1977, work was started on the various jobs associated with stripping the surface. Wooded areas in the path of the excavators and stackers were deforested, grubbed and, after an intensive search for buried shells from World War II, made available for archeological investigations. Both the routes for the large-scale equipment, belt conveyor driving stations, and conveyors were all given a thick top gravel layer. The supports for the belt conveyors were assembled on the spot, with assembly and conversion work planned and supervised by means of general and detailed network plans. The critical factor in the construction of the conveyors, which did not involve any major problems, was the vulcanizing and electrical installation work along the conveyor routes.

DEVELOPMENT PLANNING AND OPERATIONS START-UP

The first equipment group was transported on schedule from the assembly site to its point of operation on Sept. 1, 1978 (Fig. 12). Experience previously gained in starting up the large-scale 200 000-m³ (261,590 yd³) equipment in the Fortuna mine was used to insure that transport, gauging, and adjustment of the equipment caused no major problems. On Sept. 22, overburden removal started at the northwestern rim of the box cut. Three weeks later the second excavator was put into operation on the same bench, but excavating different material.

The equipment operated initially in a somewhat confined

Fig. 11. Conveyor shunting head unit with a capacity of 37 500 t/hr.

space. Pollution control called for a minimum distance of 350 m (1148 ft) to be observed between the western working rim and the conveyors installed on the site. Thanks to its design, the excavator can cut 14 m (46 ft) deep from one conveyor position in the deep step mode and as much as 17 m (58 ft) below the traveling level of the excavator in deep cut mode (Fig. 13). The conveyors are moved down into the trenches thus mined, or, if time or space do not permit the provision of space for maneuvering, relocated in the new cuts.

In the first year of development, only a relatively small dumping area was available, clearly bounded by final slopes and Federal Highway 55 to the north. Starting out from the typical cross-section for final slopes of the dump (Fig. 14), comprehensive planning was necessary to schedule the sequence of mining blocks and select the quality of the material required at the dump. To insure a stable final slope, first a 30-m (98-ft) wide drainage ditch was excavated in the center

of the safety embankment. At the bottom of the final slope, cohesive material was removed to guarantee a perfect bond between the safety embankment, forest gravel layer, and the original subsoil.

In the first year of development, problems arose primarily in using equipment in wet loose-rock layers. Throughout the development area a layer of *Reuver* clay below a 10 to 15-m (32.8 to 49.2-ft) thick alluvial gravel bed was encountered. The *Reuver* clay consists of alternating bands of varyingly cohesive strata with water-saturated fine-sand stringers below 1 to 2 m (3.3 to 6.6 ft) of residual water. The stratification of these layers ruled out prior drainage by wells. Despite extensive mine drainage measures preceding and accompanying the excavator work, overburden movement was subject to serious disruptions and performance limitations. Only after the *Reuver* clay had been completely worked through in the development area was the residual water able to percolate through to the underlying permeable strata.

Fig. 12. Equipment erection and start-up schedule for the Hambach mine.

Fig. 13. Excavating techniques.

Over one year of operations at the Hambach mine dealing with water-saturated, cohesive overburden masses not only involved various problems in mining and conveying work due to breakdowns and limits to performance, but also led to a great number of technical and organizational improvements in materials handling. The overburden, normally still lumpy when extracted, changed its consistency to become a viscous sludge, even after short distance conveying. The avoidance of transfer point plugging, belt track control, and scraper system efficiency were improved greatly by design modifications. Selective use of plastic wear parts in the side chutes of the transfer points and the installation of rubber

aprons on the baffle plates reduced material caking, and in particular, spillage.

The dump structure required extensive investigations in planning and geomechanics in order to safely and effectively dispose of the wet, cohesive mixed soil. This was especially true with regard to the confined dump space and stringent conditions governing the quality of material required to build up the final slopes. The most important requirement was the development of suitable methods to insure proper material distribution. These methods included limiting slope height and gradient, and safeguarding the stability both of the individual slopes and of the entire dump body through flexi-

NOTE

Fig. 14. Typical cross section of final slope configuration for outside dump. All elevations shown in meters.

bility in equipment utilization. Examples can be found in Fig. 15.

In the first six months of 1979, it was not possible to complete the safety embankment on the lowermost dump due to the lack of sufficient volumes of stable gravel and sand. Only in the boundary area between mixed soils and safety embankment and the area parallel to the face conveyor system was it possible to create stable polder dams in order to obtain the maximum dump space for the excessive quantities of wet mixed soils (Figs. 16 and 17). The final slope was completed from materials from the upper sections of the dump that were built up later.

Mixed soils were disposed of in well-planned, stable, polder dams which used minimum volumes of noncohesive overburden. Restoration of the load-bearing capacity of the masses dumped into the polders was effected through lengthy periods of consolidation. These geotechnical considerations, however, needed to be balanced with optimization of dumping space and the demands on system performance. From these practical considerations, an efficient method was finally devised that involved building up the dump in slices. This method, produced stable polders, maximum mixed soil dump space with individual slope heights of between 12 and 15 m (39.3 and 49.2 ft) in both high and deep dumping and extremely low slope gradients. Bench block was the operation mode for the spreaders (Fig. 16) due to the various material types encountered (Henning, 1980a). This method insured the controlled dumping of masses of low consistency and at the same time allowed greater scope for decision-making on material handling and spreader movement.

Especially problematic was the restoration of the load-bearing capacity of the cohesive mixed soils, which was done to insure equipment mobility and dump mass stability. The originally established thickness of 5 m (16 ft) for grade dumping proved to be too low. It was discovered that during dumping such a grade thickness could not always be observed, since the movement of the material in the impact area of the bulk masses falling from the spreader produced a change in the thickness and composition of the grade. The

crawlers of spreaders and tripper cars sank dangerously into the unstable soils, which in turn led to movement in the dump slopes. An increase in the firm grade to a thickness of 7 m (23 ft) and strict adherence to an adjusted dumping scheme aimed at reducing the excess pore water pressure in the polders eventually proved effective (Henning, 1980b). A typical dump-slope cross-section is shown in Fig. 17, which illustrates that on each bench permeable and/or only slightly cohesive material is required to build up the 7-m (23-ft) thick grade and the polder dams. High dumping of the upper dump bench ends with an 8-m (26-ft) thick permeable layer with the top 2 m (6.6 ft) preferably being constructed with Quaternary gravel as a substructure for loess fill. A total of 50% of the material being mined is classified as permeable material, as opposed to 40% of the material dumped at the Sophienhoehe. The 10% surplus quantity is required to insure adequate and consistent material supplies (Loeper, 1982).

In 1978, only 0.006 km³ (8.1 million yd³) of overburden was moved, i.e., less than planned. In addition to the difficulties already explained, the primary cause of the lower output was the fact that in the first four months of operation there was no night shift due to a noise pollution control order issued by the mining regulatory authorities.

From the outset, the development phases were arranged to insure optimal emission control. Prior to start-up of operations, a 7-m (23-ft) high, 3.2-km (2-mile) long protective barrier was erected on the western rim of the mine. During the initial assembly of the conveyors in the field, minimum distances of 350 m (1148 ft) between work site and houses were observed. Bench planning insured that the conveyors were relocated in the cuts made by the excavators after the shortest possible period in the field.

Nevertheless, it was not possible to avoid serious problems with the neighboring residential communities, particularly during the start-up phase. The erection of additional noise-abatement barriers and walls at the stationary conveyors near the belt distribution point at the Sophienhoehe, the replacement of all upper belt idlers with specially designed

Fig. 15. Typical dumping schemes for slope stability.

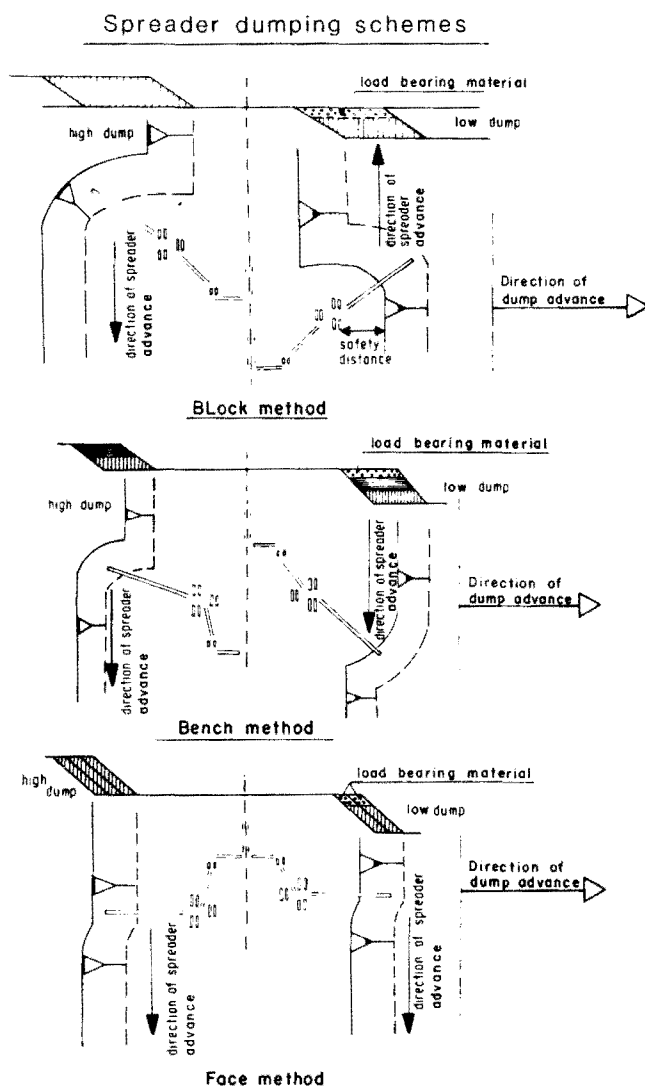

Fig. 16. Spreader dumping schemes.

machine-balanced idlers having an average reduced noise level of 7 dB (A), along with organizational measures in the deployment of equipment, all helped to attain an effective reduction in noise pollution caused by mining operations.

Later, a great number of innovative technical and organizational noise-control measures were tested and implemented at the Hambach mine. The new equipment and installations incorporate the latest technological developments and meet the technical and noise emission requirements of the mining regulatory authorities. The current developments are aimed at achieving an effective noise reduction at the sources on mobile equipment and conveyors. In addition, possibilities of reducing noise levels by shielding and covering drive units are presently under study, with special consideration given to prevailing conditions in open pit mines.

To reduce dust pollution, experiments are underway on sprinkling devices that later on will be used primarily in areas of exposed lignite. Partial reforestation of the upper mine slopes and greening of the western and southern final slope system by spraying a mixture of grass and clover seeds, granulated fertilizer, and a plastic adhesive will inhibit dust formation and at the same time provide protection from surface water erosion.

FULL-PERFORMANCE OPERATIONS

In mid-1979, the preconditions existed for the transition to full-performance operations. On the mining side, dry, sandy-gravel layers, exposed below the *Reuver* clay, were urgently required to build up the needed safety embankment on the western rim of the Sophienhohe (Fig. 18a). By contrast, the mixed-soil dump space in the center of the dump was already fully utilized. By late July 1979, 0.036 km³ (47 million yd³) of overburden had been moved under the difficult conditions of the start-up phase already described.

In August 1979, the third conveyor began operating on the outside dump. Together with the improved quality of the material, this addition led to a considerable increase in overburden output (Fig. 19b). What also became clear is how much output is dependent on the occurrence of sand and gravel masses necessary to lay out the final slopes, polder dams, and dump slope. The decrease in output in April 1980, as shown in Fig. 19b, was due to a prolonged breakdown of spreader 759, which sank into a dump slope of low bearing capacity. After difficult salvage operations, reassembly work was necessary on the machine's crawler system.

Fig. 17. Typical cross section of working benches for outside dump.

In 1979, total overburden of 0.075 km^3 (98 million yd^3) was moved at the Hambach mine. With the same equipment, overburden transport volume rose from 0.125 km^3 (163.4 million yd^3) in 1980 to 0.140 km^3 (183.5 million yd^3) in 1981. The overburden quantity of 0.079 km^3 (103 million yd^3) removed in the first six months of 1982 suggests further gains in machine capacity.

Fig. 18d show diagrams of the development work on the mine and dump including overburden movement, land used, and land reclaimed by the end of 1981. The section-wise development of the mining operations into greater depths depended very much on the overburden quality required for the outer dump, in particular, the demand for sand/gravel masses and reclaimable forest gravel for the completion of the surface in the final slope area.

The situation at the end of 1980 shows the operations after total overburden movement of 0.206 km^3 (270 million yd^3). The box cut as shown is approximately 5 km (3 miles) long, 1 km (0.6 miles) wide and as much as 70 m (230 ft) deep. The area of the future lignite bunker has been cut out by one of the $240\,000 \text{ m}^3$ (313,908 yd^3) excavators. The contours of the final slope system of the Sophienhoehe are quite prominent.

In 1981, the mine developed primarily in depth. The goal was the earliest possible excavation of the section for the new belt distribution point in the southwestern part of the box cut. Later in 1981, this cut was about 5.5 km (3.4 miles) long, 1.4 m (4.6 ft) wide and as much as 110 m (361 ft) deep. During that year, the outer dump, Sophienhoehe, grew to a height of 167 m (548 ft) (Fig. 18d). By the fall of 1981, forestry reclamation was confined to the berms and inclines of the final slope system, with a separate unit operation being set up to spread topsoil. The 1 to 2-m (3.3 to 6.6-ft) thick layer of loess in front of the dump is extracted by a small bucket wheel excavator and, after being transported over a 1000-mm (39-in.) wide conveyor, distributed by a spreader in 2-m (6.6-ft) lifts on the dump surface. The total area of 185 hectares (457 acres) reclaimed by the end of 1981 was increased by another 72 hectares (178 acres) to 257 hectares (635 acres) by the end of the planting period in April 1982. In mid-1982, the first sections of the reclaimed areas were opened to the public for recreation.

The utilization of the mining equipment's capacity has been increased almost continuously since startup of operations in 1978 (Figs. 19a and b). Crucial for the load figures obtained was the nature and quality of the overburden as well as restraints on output, which were partially influenced by the arrangement of the conveying and dumping systems. The steady improvement in working time is due to the decrease in operational disruptions during service and to the successful implementation of technical and organizational measures.

The output of the individual excavators in terms of daily, monthly, and annual overburden movement varies considerably. Over longer periods, all items of equipment have reached a rated capacity of $240\,000 \text{ m}^3$ (313,908 yd^3) based on 19.2 operating hours per day (i.e., 80% of 24 hours). The comparatively great differences in average and/or maximum daily output are due to the already mentioned factors limiting output and operating hours, namely, material quality, conveying, and dumping, the impact of which was particularly felt in the development stage of the mine. The maximum output in overburden movement reached at Hambach [$365\,700 \text{ m}^3/\text{d}$ ($478,318 \text{ yd}^3$) for one bucket wheel excavator and $933\,480 \text{ m}^3/\text{d}$ ($1,220,946 \text{ yd}^3/\text{d}$) for three equipment groups] furnishes convincing proof of the operating efficiency of the selected equipment.

Mining system downtime had a considerable influence

on machinery utilization. This downtime consisted of stand-stills attributable to the lack of receiving capacity in the spreaders caused by breakdowns and adverse material properties (Fig. 20). After the initial difficulties in the conveyor system had been overcome, system downtime fell to mid-1979 levels that were considered normal. The various causes of downtime in the conveying system were nonspecific, thus eliminating evidence for fundamental technical or organizational troublespots. Only at those conveyors with separate feed points some distance from the tail station, was downtime above average. This downtime was caused by belt damage and operational breakdowns attributable to defective belt tracking. In total, disruptions in conveyors on the dumping side were considerably higher than those in the conveyors on the mining side. These higher values correspond directly to deterioration of the wet, cohesive material during transport as well as to the difficult grade conditions under which the tripper cars (on the dumping side) operated.

The operational control center (*BU*) of the Hambach mine is where all operations information is collected. A single room houses the operational control center, breakdown center, radio center, and belt control station. Central recording, identification, and evaluation of downtime and performance data from the mining and conveying systems is carried out by a process computer. Intersystem communication is an important precondition for the control and monitoring of operations and subsequent feedback to mine planning. Further development of computerized decision aids for mine operations control at Hambach will be an important task in the years to come. These developments include modified processes of operational control which, for example, will allow a faster retrieval of survey data than was previously possible.

Due to the increase in volumes transported, a higher probability of damage occurring and the greater risk of consequential damage, more attention is being paid to the continuous local supervision of equipment and conveyors. Automatic conveyor monitoring instrumentation, having widespread use in the Rhenish mining area (for spillage, belt tension, slippage, excess load, excess torque, and positioning of transfer points on shunting heads, etc.) is employed, as well as a mobile staff of monitoring personnel. During the start-up phases, which were affected by temperature extremes and adverse material properties, further stationary monitoring personnel were temporarily required at critical points, such as belt distribution points, separate transfer points, and cleaning facilities. The use of automated control for belt tracking, caking, and damage detection (in particular, longitudinal cracks, still not adequately solved) will mean the development of improved equipment able to meet tough operational requirements.

The equipment at the Hambach mine has proved to be successful in full operation. Technical and organizational developments in the mine's maintenance sector are being carried out with priority given to improving operational safety and economics. In the mechanical sector, current efforts are mainly centered on belt transfer points, pulley linings, equipment traveling gears, vulcanizing techniques, and pollution control.

Modifications at the belt transfer points have improved operating conditions along with a decreased incidence of damage and tracking difficulties. These modifications include use of raised separate impact sections; installation of top chutes with modified longitudinal sealing; change in type of garland-type impact idlers; and insertion of rubber aprons in front of the baffle walls.

Results of the initial experiments with automatic belt-track controls have proven promising. The wear of the pulley

SURFACE MINING

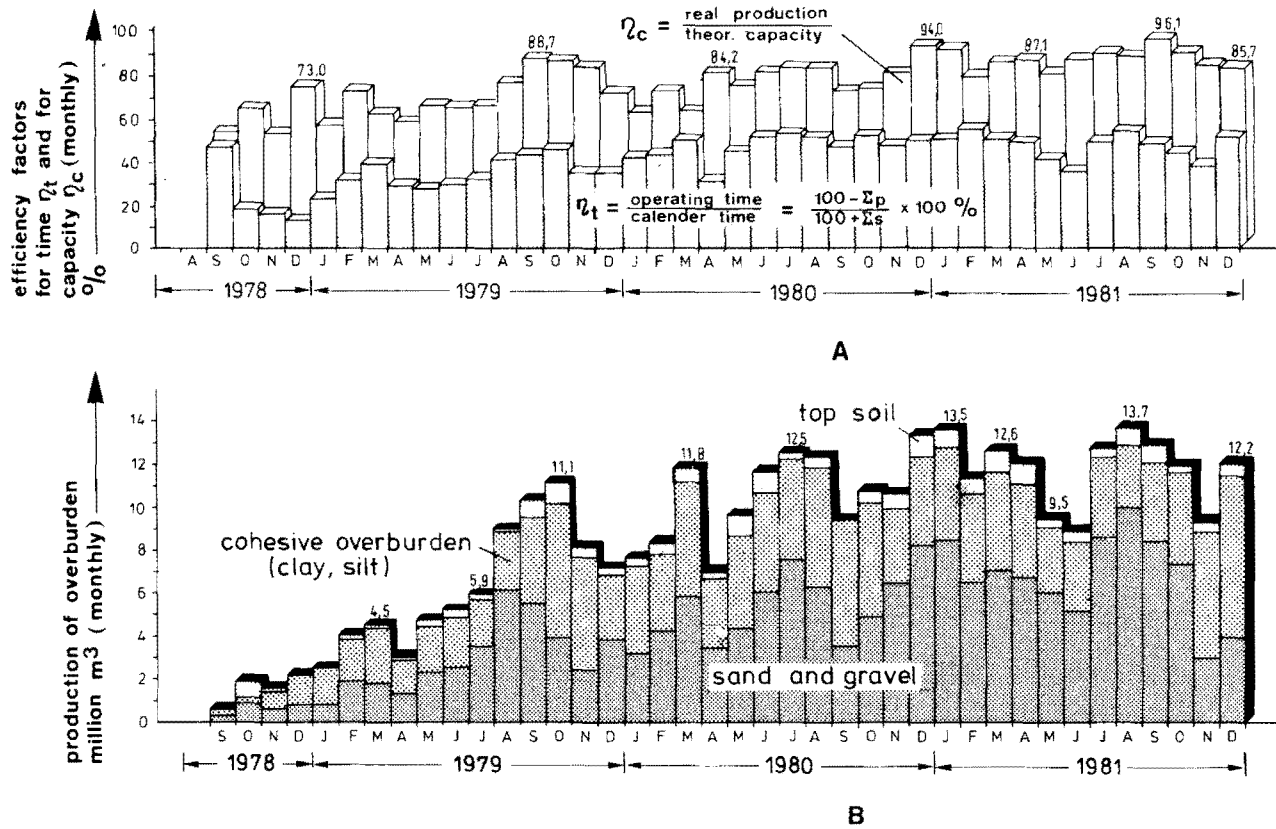

Fig. 19. Development of overburden production and efficiency factors for time (η_t) and for capacity (η_c) of the excavators, 1978-1981, monthly.

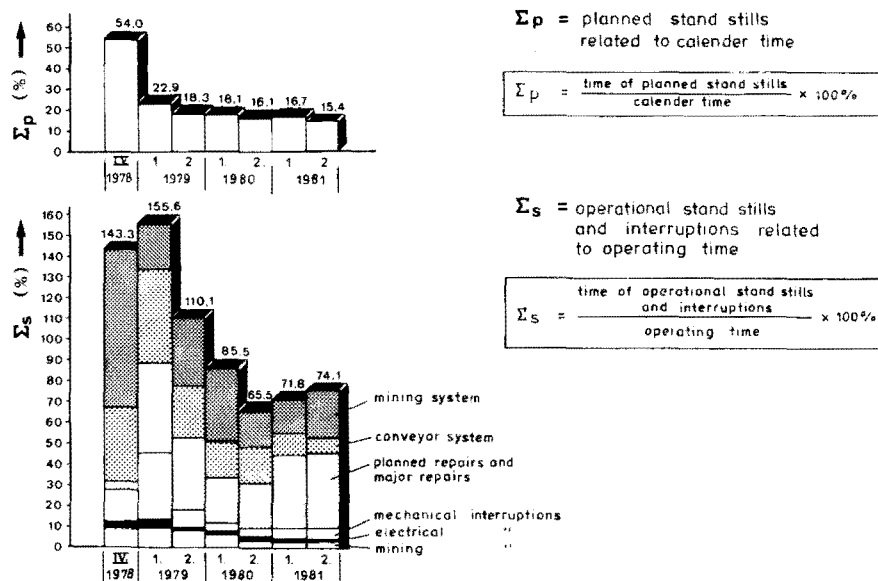

Fig. 20. Standstills and interruptions of the excavators, 1978-1981.

linings, mainly due to material return and belt contamination, will be reduced through improved belt tracking and by the use of scrapers and more stable linings. In order to prolong service life, structural improvements on the traveling gear and driving sprocket have begun. Plans to improve belt maintenance include a more rigorous defect detection schedule. In the field of cold repairs, further developments are being pursued with the object of developing quicker and more durable bonding techniques. In current developments of efficient noise barriers and cladding for the drive units of equipment and conveyors, attention is focused not only on the solution of various difficult structural tasks, but also in the design such that these new facilities do not present new problems associated with the operational safety and maintenance of machine parts.

The electromechanical facilities at Hambach did not show any special weak points in full performance operations. The conveyors are controlled by microprocessors that operate for each conveyor route. Aside from a few initial difficulties with software and the training of maintenance personnel, the new systems proved advantageous over conventional solutions with reference to troubleshooting, periods of disruption, maintenance, and adjustments to changing operational conditions. This was also true of the connection of conveyor routes to the peripheral equipment of the process computer in the operational control center via serial data interfaces.

The assembly of an experienced workforce was one of the chief preconditions of a successful operations start-up at the Hambach mine. Nearly half the present staff was obtained through transfer of experienced personnel from other mines. The majority of the staff, some of whom had been trained in other mines for their work at Hambach, live in nearby communities. The rest of the staff was taken from the labor market. In the future, more emphasis will be placed on taking employees from Rheinbraun's training centers and *Jungwerker* (young worker) departments. The training of new staff members and young personnel has made great demands on the experienced personnel, particularly on the supervisory staff. Prospects of promotion in a new mine have greatly enhanced staff involvement in the difficult start-up phase.

The downtime for scheduled maintenance and scheduled repairs is considered high, reflecting the problems of maintenance organization in an open pit mine under development. Greater time is spent on performing necessary wear-related repairs than would be expected in a fully operational mine, due mainly to the small number of conveyor flights and a comparatively small maintenance staff. The increase in repair time from the second half of 1980 was caused by the replacement of the bucket wheel shaft in excavator 288. This repair took 10 weeks between early May and mid-July, contributing to the decline in the performance efficiency in this period.

Between September and November 1981, declines in performance efficiency were experienced due to lengthy repairs on the bridge suspension of spreader 757, thus matching three excavators with only two spreaders.

The trends in reducing the number of operational, mechanical, and electrical breakdowns have been encouraging. In individual cases, there were deviations from the average values shown for traveling gears, (especially crawler plates), as an interaction between equipment and difficult grade conditions, and also for cleaning facilities on excavators and spreaders.

In new mine developments, the course of operations is very much affected by planning, execution of the first assembly, and relocation of conveyors. Fig. 21 shows developments in conveyors with a breakdown for newly constructed conveyors, operating conveyors, and relocated and reassembled

conveyors. The dumping section in particular frequently required changes at short notice in the belt routing and in some cases a disproportionate amount of reassembly work, resulting from comparatively small effective dumping space from one conveyor position and the already mentioned problems of geomechanics and material behavior. The comparatively small share of dismantling and reassembly as a primary cause of downtime in the conveyor system shows satisfactory coordination of the selected planning and operational measures.

In 1979, nine new conveyors with a total length of 21 km (13 miles) came on line. Some 11.8 km (7.3 miles) of conveyors were reassembled in 31 operations, involving 21 conveyor shifts made over a 1.8-sq km (0.69 sq-mile) area. In 1980, four new conveyor routes, 5.1 km (3.2 miles) in length, were put into operation. In 18 projects, 13.9 km (8.6 miles) of conveyors were reassembled; the 55 required conveyor shifts covered an area of 6 sq km (2.3 sq miles) without seriously disrupting operations. The same area was shifted across in 1981, with the number of conveyor shifts falling to 47. The conveyor reassemblies continued in 1981 as well, covering almost the same total distance as the new conveyor routes, thus yielding a total of more than 35 km (21.7 miles) installed so far.

To prepare for the fourth excavator as well as start-up of the first conveyor link to the Fortuna mine and the first lignite conveyor, work began on extensive new conveyor constructions in mid-1982. The new belt distribution point is being gradually enlarged and by the time the overburden transport to the Fortuna and Bergheim dumps has stopped after the year 2000, it will have the configuration shown in Fig. 22.

What proved to be very advantageous for the quick and safe reassembly of the conveyors were the mobile crawlers used in transport of the head and tail stations (Henning, 1977). The smaller crawlers used for the first time at Hambach for powered tail stations of 210 t (231 st) service weight have proven to be especially useful. Even shifts into cuts with slope gradients of 1:5 have not met with any particular problems during shifting or maintenance work. The system of 30/6-kV transformers and power switches mounted on the head and tail stations chosen at Hambach has the advantage that conveyor shifts no longer require special preparation time for the power supply, prior and after the actual shifting is carried out.

The techniques of advance planning daily equipment use and organizing mining operations already in service in Rheinbraun's other mines have also proven to be an unqualified success at the Hambach mine (Henning, 1977; Henning and Schenk, 1977; Krug, 1980). This is especially true of excavating in areas of fault zones or potentially unstable slopes. One special advantage of the 240 000-m³ (313,908-yd³) excavators is their rapid advance rates minimizing standing time on or near potentially unstable slopes.

Great demands are made by the high capacities of the large-scale equipment on the scheduling requirements for equipment and the continuous monitoring of operations; in particular: the restricted maneuvering space in dumping operations as related to slope conditions; permissible changes in material; output planning limits resulting from calculated load intervals in mass spreading; and necessity of frequent equipment changes to avoid dangerous operational situations (slopes). These all call for flexible operations planning and a comprehensive overview of operations by all management personnel.

The operational control center (*BU*) of the Hambach mine is where all operations information is collected. A single room houses the operational control center, breakdown cen-

Fig. 21. Development of the belt conveyor system, 1978-1981.

ter, radio center, and belt control station. Central recording, identification, and evaluation of downtime and performance data from the mining and conveying systems is carried out by a process computer. Intersystem communication is an important precondition for the control and monitoring of operations and subsequent feedback to mine planning. Further development of computerized decision aids for mine operations control at Hambach will be an important task in the years to come. These developments include modified processes of operational control which, for example, will allow a faster retrieval of survey data than was previously possible.

Due to the increase in volumes transported, a higher probability of damage occurring and the greater risk of consequential damage, more attention is being paid to the continuous local supervision of equipment and conveyors. Automatic conveyor monitoring instrumentation, having widespread use in the Rhenish mining area (for spillage, belt tension, slippage, excess load, excess torque, and positioning of transfer points on shunting heads, etc.) is employed, as well as a mobile staff of monitoring personnel. During the start-up phases, which were affected by temperature extremes and adverse material properties, further stationary monitor-

ing personnel were temporarily required at critical points, such as belt distribution points, separate transfer points, and cleaning facilities. The use of automated control for belt tracking, caking, and damage detection (in particular, longitudinal cracks, still not adequately solved) will mean the development of improved equipment able to meet tough operational requirements.

The equipment at the Hambach mine has proved to be successful in full operation. Technical and organizational developments in the mine's maintenance sector are being carried out with priority given to improving operational safety and economics. In the mechanical sector, current efforts are mainly centered on belt transfer points, pulley linings, equipment traveling gears, vulcanizing techniques, and pollution control.

Modifications at the belt transfer points have improved operating conditions along with a decreased incidence of damage and tracking difficulties. These modifications include use of raised separate impact sections; installation of top chutes with modified longitudinal sealing; change in type of garland-type impact idlers; and insertion of rubber aprons in front of the baffle walls.

Results of the initial experiments with automatic belt-

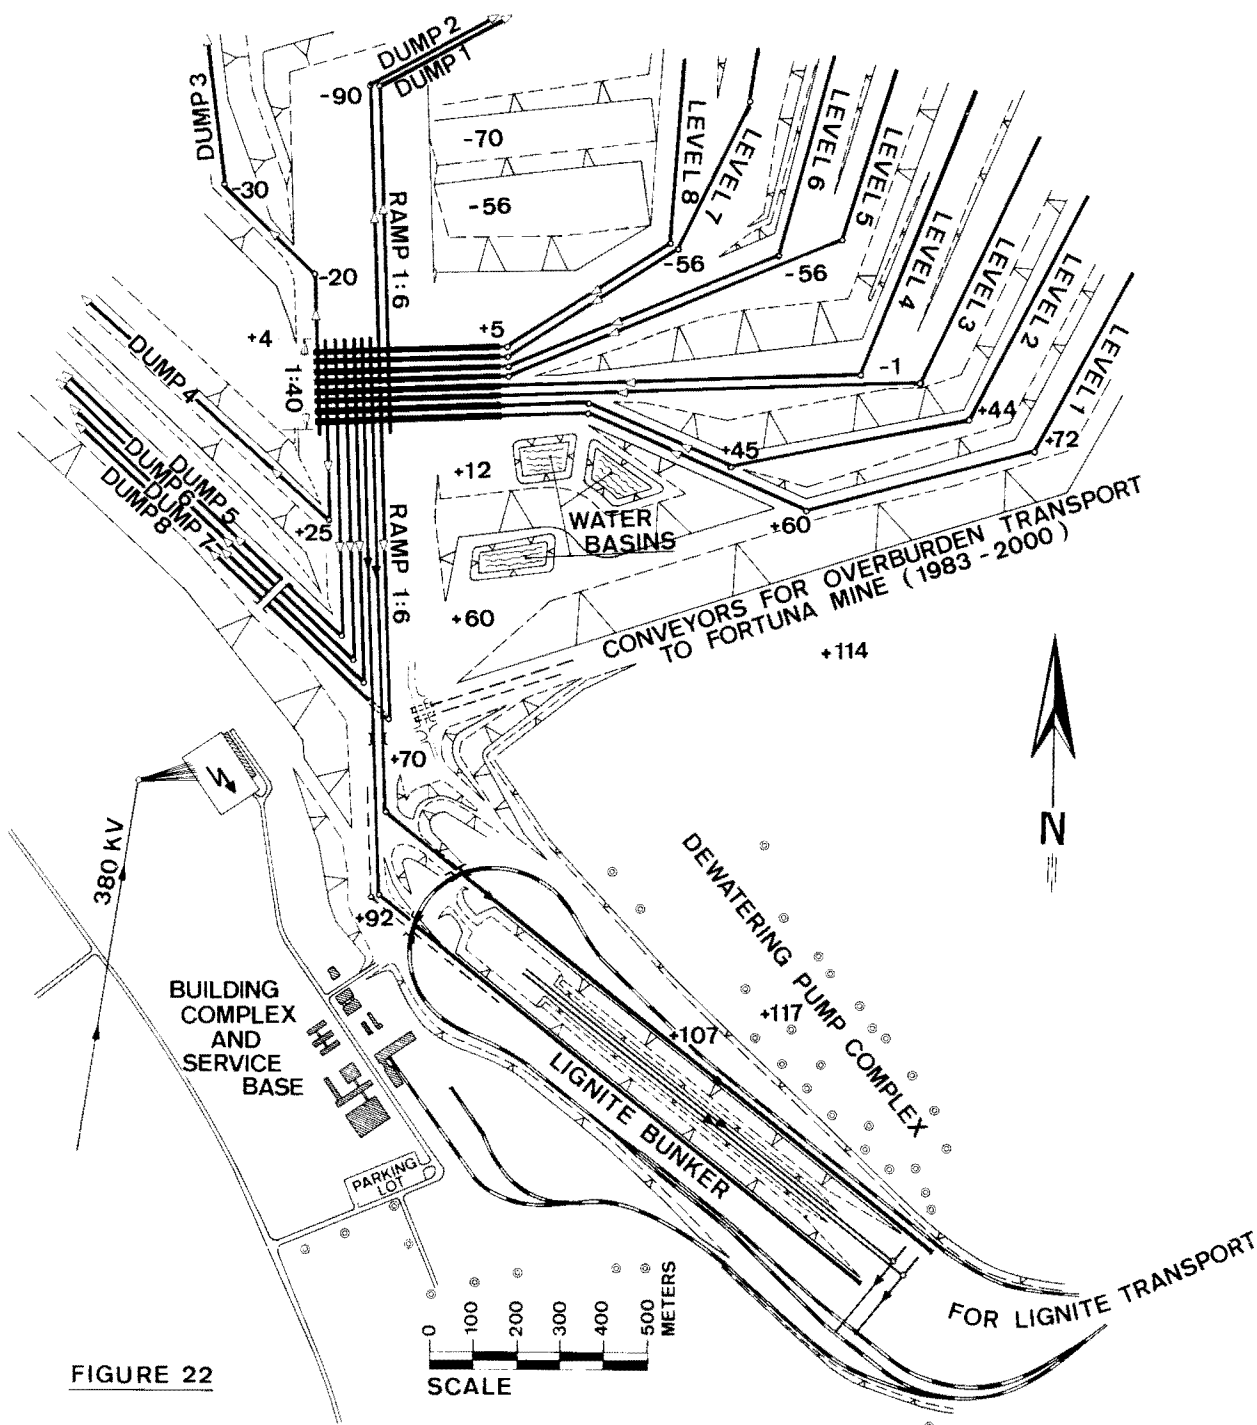

FIGURE 22

Fig. 22. Distribution point with connection of eight excavating and eight dumping units.

track controls have proven promising. The wear of the pulley linings, mainly due to material return and belt contamination, will be reduced through improved belt tracking and by the use of scrapers and more stable linings. In order to prolong service life, structural improvements on the traveling gear and driving sprocket have begun. Plans to improve belt main-

tenance include a more rigorous defect detection schedule. In the field of cold repairs, further developments are being pursued with the object of developing quicker and more durable bonding techniques. In current developments of efficient noise barriers and cladding for the drive units of equipment and conveyors, attention is focused not only on

the solution of various difficult structural tasks, but also in the design such that these new facilities do not present new problems associated with the operational safety and maintenance of machine parts.

The electromechanical facilities at Hambach did not show any special weak points in full performance operations. The conveyors are controlled by microprocessors that operate for each conveyor route. Aside from a few initial difficulties with software and the training of maintenance personnel, the new systems proved advantageous over conventional solutions with reference to troubleshooting, periods of disruption, maintenance, and adjustments to changing operational conditions. This was also true of the connection of conveyor routes to the peripheral equipment of the process computer in the operational control center via serial data interfaces.

The assembly of an experienced workforce was one of the chief preconditions of a successful operations start-up at the Hambach mine. Nearly half the present staff was obtained through transfer of experienced personnel from other mines. The majority of the staff, some of whom had been trained in other mines for their work at Hambach, live in nearby communities. The rest of the staff was taken from the labor market. In the future, more emphasis will be placed on taking employees from Rheinbraun's training centers and *Jungwerker* (young worker) departments. The training of new staff members and young personnel has made great demands on the experienced personnel, particularly on the supervisory staff. Prospects of promotion in a new mine have greatly enhanced staff involvement in the difficult start-up phase.

Early in 1978, the Hambach mine, with some 170 employees, became an operational unit within Rheinbraun's western group. Further staff developments for the mining, maintenance, and technical administration sectors are shown in Fig. 23. Late in 1981, some 1100 persons were employed at the Hambach mine. To this number must be added 150 employees working for Hambach in the mining group's commercial administration. As more equipment and conveyors are installed and operated, staff size will also increase. In the mid-1990s, when eight large-scale equipment groups and conveyors of about 100 km (62 miles) in length will be operational, the Hambach mine will have a projected workforce numbering nearly 2500.

Hambach's plant and equipment has been extended according to plan. The fourth excavator, the assembly of which began in May 1981, and the first overburden conveyor to the Fortuna mine, became operational in 1983. The first lignite was mined in that year. Lignite bunkers, train loading systems, and the Hambach railroad users have been completed. So has the extension of the stationary belt distribution line into the mine's slewing point and the installation of the second conveyor to Fortuna. The build-up of the first inner dump and the start-up of the fifth excavator will soon be completed. Present progress made in planning and implementing these projects suggests that they can be carried out on schedule.

Capital expenditures on mine development, equipment, and other facilities, including projected inflation, will total some 5 billion DM (Deutsche Mark) by 1990. By the end of 1981, some 1.2 billion DM had been invested in equipment for the Hambach mine. Including development costs of about 750 million DM incurred in the same period, the Hambach mining project, having cost some 2 billion DM so far, has become Rheinbraun's single most important capital spending item.

SUMMARY

Development of the Hambach open pit lignite mine began in the western sector of the 85-sq km (32.8-sq mile) large

Fig. 23. Personnel development, 1978-1981.

mining area (the so called *Erft Block*) that has lignite reserves of 2.5 Gt (2.8 billion st) and an overburden-to-lignite ratio of 6.2:1. Starting in September 1978, three large-scale equipment groups with rated capacities of 240 000 m³/d (313,908 yd³/d) each were successively put into operation. In the first year of the development phase, numerous equipment disruptions occurred due to the wet, cohesive overburden being excavated and difficulties in maintaining stable pit slopes. Full operations were started in August 1979. By the end of 1981, overburden volume totalling some 0.347 km³ (454 million yd³) had been moved. Valuable operational experience in development work was gained in the following areas: planning and performance of extensive assembly and reassembly jobs, solving difficult problems in geomechanics, noise pollution abatement, and personnel training. On the whole, development work at the Hambach mine is being carried out according to plan.

9.3 Case Study of Palabora Mining Company Ltd.

A. J. LEROY AND J. W. LILL

INTRODUCTION

General Description

The company operates a large open pit mine and associated copper processing facilities in the Transvaal Province of The Republic of South Africa. The complex is situated close to the town of Phalaborwa at latitude 24°00'S and longitude 31°07'E. The road distance from Johannesburg is 550 km while the rail distance to the nearest port, Maputo in Mozambique, is approximately 340 km (Fig. 1.).

The open pit copper mine (Fig. 2) is geared to produce 307 kt/d of material on a six-day week basis to feed a continuous milling and flotation operation at a rate of 80 kt/d of ore. Other works include a magnetic separation plant for the removal of magnetite, a heavy minerals plant with its associated chemical treatment sections, a conventional coal-fired smelter with its attendant sulfuric acid and gas scrubbing plants, an electrolytic refining tankhouse with a capacity of 142 kt/a, and a modern continuous copper rod casting plant which serves the needs of South Africa's copper wire and cable industries. A vermiculite open pit mining operation and beneficiation plant form part of the integrated complex which is manned by some 3900 employees. High quality refined copper is marketed as cathode and continuous cast rod. Byproducts from the copper operation are uranium calcine, zirconium compounds, reground magnetite for use in coal preparation plants, sulfuric acid, refined nickel sulfate, and refinery anode slimes. The latter contain gold, silver, platinum, and palladium. The vermiculite operation produces concentrates in six commercial size fractions.

DISCOVERY OF THE COPPER DEPOSIT

Archaeological Investigations

It has been shown that the ancients recovered copper from the ore body on Loolekop Hill over 1000 years ago. They dug and transported oxide copper ore, predominantly as malachite, to syenite hills close by. The copper was smelted in primitive but effective clay furnaces.

Modern Exploration

A prospector, Carl Mauch, was the first to record the copper occurrence while carrying out reconnaissance mapping of a portion of the Transvaal Province and of Zimbabwe during the period 1868-1871. More detailed exploration was not made until 1912 when Hans Merensky initiated an investigation aimed primarily at the occurrences of vermiculite and apatite which were found at Loolekop and in the immediate vicinity. Merensky continued to feature prominently in developments in the Phalaborwa area until 1951.

Phosphate mining was commenced in 1932 in a valley below Loolekop Hill but the operation failed after the extraction of 4500 t. In August 1939, the Transvaal Ore Co. Ltd. was formed for the purpose of exploiting the known vermiculite occurrence. This company was acquired from the Hans Merensky Trustee Co. by Palabora Mining Co. Ltd. and became a subsidiary of the latter on May 10, 1963.

Merensky continued his investigations to prove the economic viability of recovering phosphates and during the latter 1940s and early 1950s made extended efforts to dispose of his claims. Ultimately during 1951, the Industrial Development

Corp. of South Africa, at the request of the government, financed a new company, The Phosphate Development Corp. Ltd. (FOSKOR).

FOSKOR was created with the objective of exploiting the Phalaborwa phosphates in order to produce a concentrate which would satisfy the fertilizer requirements of South Africa. This objective has been successfully achieved. During 1952, the Geological Unit of the Energy Board discovered the presence of uranothorianite in the carbonatite on Loolekop. During the ensuing few years the Dept. of Mines and the Geological Unit conducted a prospecting program which included some underground development and surface diamond drilling. It was established that the radioactive minerals were of no economic significance but that copper mineralization could render the deposit valuable.

Local mining companies showed only mild interest in this low-grade copper deposit where the values were 1% or less. The techniques of exploiting large tonnages of low-grade copper ore at shallow depths were very different from the deep level underground operations at which South African engineers were adept. Elsewhere in the world, notably in the Americas, mining companies had acquired wide experience in operating low-grade open pit copper mines with their related financial and technical problems. At that time some argued that copper was already overproduced; seemingly to confirm this, the London Metal Exchange fixings plunged from over R800 per long ton to R320 between 1955 and 1958. It was against this background that two prominent overseas mining groups, the Rio Tinto-Zinc Corp. of London (RTZ) and the Newmont Mining Corp. of New York, became interested in a closer study of the Loolekop copper occurrence. Palabora Mining Co. Ltd. (PMC) was registered in August 1956 to carry out this task.

GEOLOGY

Geology of the Palabora Igneous Complex

The Palabora igneous complex (Fig. 3) located in the Archean Shield of northeastern Transvaal is unique among

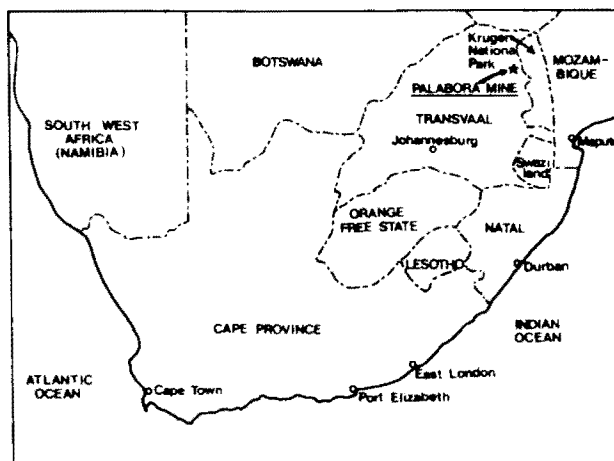

Fig. 1. Location of Palabora copper mine in southern Africa.

Fig. 2. Aerial view of open pit.

the many described African alkaline complexes in that its carbonatite member is the site of an economic deposit of copper ore. Magnetite, uranothorianite, baddeleyite, gold, silver, and nickel sulfate are subsidiary products of the copper mining venture, while the ultramafic rocks of the complex are host to economic deposits of apatite and vermiculite.

The complex resulted from an alkaline intrusive cycle which emplaced, in successive stages, pyroxenite, syenite, and ultrabasic pegmatoids. The age of the complex is generally assumed to be greater than 2060 million years. Pyroxenite intruded first in a north-south elongated, kidney-shaped stock which covers an area of approximately 1655 ha, i.e., roughly 6.4 km N-S by 2.6 km E-W. A corona of feldspathic pyroxenite, formed by interaction with the Archean gneiss country rock, is peripherally distributed. Syenite plugs were forcibly injected into the gneiss surrounding the main pyroxenite mass and this phase was followed by an extended period of non-violent and partly metasomatic activity which formed irregular, vertically disposed pegmatoids at three centers in the pyroxenite pipe and caused some fenitization of the Archean gneiss in contact with the pyroxenite. During this period the foskorite and banded carbonatite in the centrally located pegmatoid body were emplaced.

Subsequent fracturing of the consolidated infilling of this latter subsidiary pipe and renewed igneous activity led to the intrusion of a dike-like body of transgressive carbonatite at the intersection of two prominent fracture zones and a stock-work of transgressive carbonatite veinlets crosscutting the older rocks along preferred trends. Intensive post-carbonatite fracturing along preexisting zones of rupture provided channels for copper-bearing mineralizing solutions to permeate the carbonatite-foskorite pipe infilling with veinlets of copper sulfide and other subsidiary minerals.

The ultrabasic pegmatoid bodies consist of two main rock types with constituent minerals in varying proportions, i.e., an olivine-phlogopite-diopside rock and a diopside-phlogopite-apatite rock. In places the constituent minerals of these rocks attain pegmatoid dimensions. Hydration of the phlogopite in the weathered zone of the pegmatoid bodies has formed commercial deposits of vermiculite. Apatite is an important constituent of pyroxenite, foskorite, and some of the pegmatoid rocks, attaining economic concentrations over large areas.

The complex was subsequently invaded by a number of northeast trending dolerite dikes of Karoo age.

Structure and Lithology of the Loolekop Copper Ore Body

The ore body is an elliptically shaped vertical pipe intrusive into the central core of the Palabora igneous complex (Figs. 4 and 5).

Unlike the central core, the Loolekop pipe is elongated in an east-west direction and is 1.44 km long by 0.80 km wide. It is a composite intrusion with the following age sequence: foskorite, banded carbonatite, and transgressive carbonatite. The pipe has a concentric interbanded structure.

Foskorite is composed of olivine, magnetite, apatite, and phlogopite. Magnetite makes up on average about 30% of the mass, while apatite with a small fluorine content constitutes about 15%. The phlogopite is normally present in subordinate amounts. Apart from carbonatite veining, the foskorite contains numerous irregularly shaped patches of calcite. The constituent minerals are very variable in proportion, the magnetite content, for instance, rises to well over 50% in places. In other areas, considerable masses are composed almost entirely of olivine.

Banded carbonatite is essentially composed of magnetite-rich sövite with minor amounts of apatite, dolomite, chondrodite, olivine, phlogopite, and biotite. The magnetite comprises some 20% of the rock. This carbonatite is characterized by a crude banding caused by alignment of the magnetite and accessory minerals in rudimentary layers concordant with the concentric banding of the overall lithological structure.

Transgressive carbonatite is mineralogically very similar to the banded variety but lacks the crude mineral banding. Its diagnostic feature is the crosscutting, clearly intrusive relationship to the foskorite and banded carbonatite.

The highest concentration of copper sulfide minerals occurs in the transgressive carbonatite. In descending order of abundance, the primary copper sulfide minerals are chalcocite, bornite, cubanite, vallerite, and chalcocite.

Titanium is present in solid solution with the magnetite and also in the form of titanium minerals. The magnetite which is associated with the transgressive carbonatite has an average titania content of less than 0.5% whereas the titania content of magnetite in foskorite may exceed 5.0%. Weathering of the copper sulfide minerals was generally limited in depth to a few meters. This, coupled with the fact that high grade ore outcropped on Loolekop, greatly reduced the pre-production mining tonnage required before start-up.

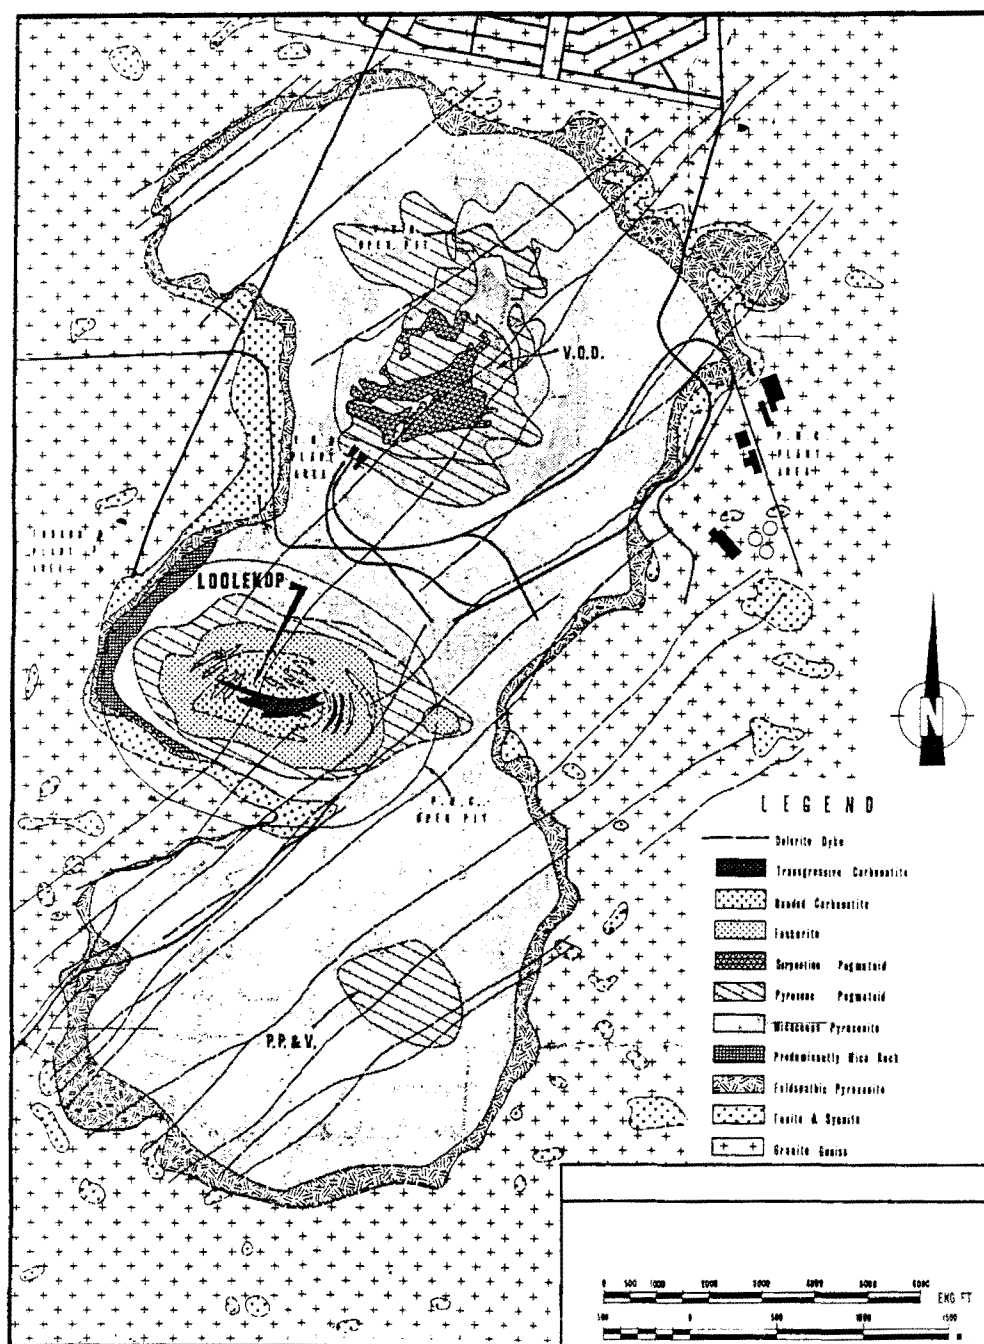

Fig. 3. Plan of geology of the Palabora Igneous Complex.

GEOLOGICAL EXPLORATION AND METALLURGICAL EVALUATION OF THE ORE BODY

General

The initial investigations commenced in June 1957 and were completed in September 1962. These investigations included surface diamond drilling, underground diamond drilling and bulk sampling, laboratory-scale metallurgical testing, and the operation of a pilot plant. These investigations proved

the existence of a large reserve of copper ore which could be processed by conventional crushing, grinding, and flotation techniques to provide a concentrate suitable for smelting.

Surface Diamond Drilling

Initially 108 inclined surface diamond drill holes, with a total length of 373 km, were drilled on sections at intervals of 76.2 m on the long axis of the ore body. These holes gave coverage to a vertical depth of approximately 366 m below the crest of Loolekop Hill or roughly 305 m below general ground surface.

A further three deep holes, which intersected the ore body at a vertical depth of 914 m and indicated that the ore body had a remarkable vertical continuity in respect of lithology, mineralogy, and mineral grades, were drilled in late 1962.

This remarkable vertical continuity was confirmed by later diamond-drilling campaigns. In 1970, a further 20 inclined holes with a combined length of 17.3 km were completed. These holes provided detailed ore body coverage to a vertical depth of 610 m below surface. During 1976, six additional holes intersected the ore body at a vertical depth of 1.2 km below surface.

Early Bulk Sampling and Metallurgical Investigation

Numerous laboratory-scale metallurgical tests carried out on core drill samples, from various locations and depths in the ore body, indicated a relatively high recoverability of copper sulfide minerals.

An underground sampling campaign became necessary to obtain bulk samples for treatment in a pilot plant in order to confirm the laboratory tests and suggested metallurgical processes. The campaign served two other essential purposes. First, it made it possible to check the accuracy of underground borehole samples against the corresponding bulk sample grades and, second, the validity of the grade projections from the surface boreholes on which the ore reserve computations were based could be verified. Mineralogical

and grade distribution studies showed that a complete horizontal section through the ore body at any elevation was representative of the ore body as a whole, because of the strong vertical continuity.

The elevation of the bulk sampling level was 122 m below the crest of Loolekop which protruded some 60 m above the average surface level. A shaft, 76 m deep, was sunk at the base of the hill and from this 665 m of access drives and 1.8 km of bulk sampling crosscuts were driven. Of the 7.1 km of horizontal diamond drilling carried out, 1868 m were in advance of bulk sampling crosscuts and the remainder were beyond and between the crosscuts.

Pilot-plant operation confirmed the results of laboratory metallurgical testing while the grade comparisons noted previously proved to be most satisfactory.

In May 1962, Palabora Mining Co. Ltd. obtained the services of two firms of international repute, Bechtel and Western Knapp Engineering, to perform an independent analysis of the work carried out to date. The Joint Venture report, received in January 1963, concluded that the investigations carried out by the company had been done in accordance with accepted and sound procedures and that the pilot-plant results could be reasonably reproduced in full-scale operation.

The Joint Venture companies were subsequently appointed to complete the detailed engineering design and to undertake the construction of the copper processing plant

Fig. 4. Lithology of the Loolekop deposit.

Fig. 5. Section through Loolekop ore deposit.

(including all auxiliary facilities) under the overall supervision of Palabora Mining's staff and senior engineers from the major sponsoring shareholders.

FEASIBILITY STUDIES

Introduction

Given that any operation mounted at Palabora would be extremely large by South African standards and in a copper ore body quite unlike those being exploited elsewhere, it was highly desirable to reassure all other prospective major shareholders that most of the possible technical problems had been anticipated. Thus, during the geological and metallurgical investigation period at Phalaborwa, the company not only used expertise existing within the parent groups but also engaged many eminent engineers from the various disciplines as consultants.

Feasibility Studies

Initial feasibility studies indicated that the proven ore reserves to a depth of 366 m could support an open-pit mining operation that would have a life of some 25 years when processing 27.2 kt per mill day. The final feasibility study, which resulted in the issuing of a Palabora Mining Co. prospectus and offer of sale of certain shares and debentures in July 1963, made the following proposals:

- An open pit would be developed containing 285.8 Mt of ore with an average grade of 0.68% copper. The average waste to ore ratio was calculated at 0.89:1. The pit would have a final depth of 305 m below general ground level, while

its surface measurements would be approximately 1.5 km by 915 m. Overall final pit slopes were approximately 45°.

- The concentrator would be capable of processing 29.9 kt/d of ore. During the initial five-year period of operation the ore grade was estimated to be 0.79% copper using a copper cutoff grade of 0.40%. In the following nominal ten-year period the average grade of the ore would be 0.65% copper based on a cutoff grade of 0.30%.

- Annual production of anode and/or blister copper would average 72.6 kt/a for years one through five and 61.7 kt/a thereafter.

- At these milling rates the life of the project would be approximately 26 years.

The major facilities to be provided were: open-pit mine facilities and services, primary crushing plant, coarse ore storage, secondary and tertiary crushing plant, copper concentrator, coarse magnetite concentrate separation and stockpiling facilities, copper smelter with blister and anode-casting facilities, waste heat boiler and associated generating plant, maintenance shops, warehouse, laboratory and offices, an acid plant, and miscellaneous utilities.

The estimated capital cost of the project was:

	Rand, millions
Capital expended to March 1963 (including preliminary expenses)	3,806
Purchase price of property	4,475
Underwriting commission	0,170
Preproduction mine development	2,104

Table 1. Comparison of Copper and Byproduct Output from Palabora Ore in Year of First Production and 1986

	Year of first production	Annual production		Period years
		First year, t	1986, t	
Copper				
Copper ore treated	1966	10 900 000	29 412 000	21
Anode copper	1966	61 900	107 553	21
Cathode copper	1968	37 200	104 800	19
Copper casting	1968	27 900	67 400	19
Byproducts				
Sulfuric acid (100%)	1966	46 300	147 100	21
Magnetite concentrate	1966	2 300 000	8 450 000	21
Anode slimes, precious-metal content	1968	5.1	17.0	19
U308 Calcine	1971	60.8	185.4	16
Baddeleyite processed to chemicals	1974	3 100	12 000	13

Mine plant and equipment	7,933
Process plant and equipment	39,722
Overhead and administration costs during construction	2,150
European housing and amenities	1,600
Loan interest during the construction period	3,150
Cash required for initial production	8,320
Expenses of raising capital funds, transfer, and stamp duty	0,280
Grand total	73,710

Equipment Loans	4,207
Overdraft facilities to be provided by Barclays Bank for working capital	8,500
Total	73,710

In connection with the foregoing it should be noted that:

- The total did not include R2 400 000 to be raised by way of first mortgage loans from building societies on 445 white employee houses in the town of Phalaborwa together with bachelor quarters and other amenities.

- Housing for black employees was to be constructed by the government at no cost to the company in the town of Namakgale and leased by the government to the employees.

- A railway spur line from Hoedspruit to Phalaborwa had been completed by the South African Railways system in late 1962. The company had made suitable arrangements with the South African Electricity Supply Commission (ESCOM) for the necessary power supply to the project. Other arrangements had been made to secure adequate water supplies from a barrage to be erected on the Olifants River.

- The construction period was expected to last for approximately three years.

PROJECT FINANCE

Capital Sources

It was proposed to raise the necessary capital as follows:

	Rand, millions
Ordinary share capital including share premium (28 220 000 shares)	29,128
Sale of 6.5% mortgage debentures (126 250 units of R100 each)	12,625
Loan from Kreditanstalt fuer Wiederaufbau (108 million Deutsche Marks)	19,250

The authorized share capital of the company was 28.5 million shares of R1.00 each. Of the total number, 24.72 million were held by the sponsoring shareholders, predominantly RTZ and Newmont. A further 2.50 million shares would be taken up in equal amounts by The South African Industrial Development Corp. (IDC), S.A. Mutual, and Sanlam. The latter two concerns were mutual life insurers.

One million shares were placed on the open market on the condition that each subscriber was obliged to subscribe simultaneously for four debentures and 100 shares or any multiple thereof.

A further 86 250 debentures would be taken up by the IDC, S.A. Mutual, and Sanlam in equal amounts.

The shares placed on the market and those taken up by the three concerns noted commanded a premium of 25¢ a share. Kept in reserve, and at the Board of Directors disposal, were a further 280 000 shares.

If required, the Board was authorized to raise additional capital by the issue of three million 7% cumulative redeemable preference shares of R1.00 each at par. In the event that yet more capital was required to bring the project into production, the sponsoring shareholders undertook to provide loans bearing interest of not more than 7.5%.

The large loan from the German Corporation, Kreditanstalt fuer Wiederaufbau was secured, inter alia, by a notarial bond by pothecating the company's interest in certain moveable assets and for the pledge of the entire share capital of the Transvaal Ore Co. (the vermiculite operation) authorized at approximately four million Rand. An agreement was signed in May 1963 between the company and Norddeutsche Affinerie in which the company agreed to sell to the latter 572 kt of blister copper. In the following month, a further agreement was entered into between the company, Kreditanstalt fuer Wiederaufbau and Norddeutsche Affinerie in terms of which the company assigned its rights under the contract with Norddeutsche Affinerie as security for payment of amounts due to Kreditanstalt fuer Wiederaufbau in terms of the provisions of the agreement with the latter.

CONSTRUCTION, START-UP, AND SUBSEQUENT HISTORY

Construction and Start-up

Financing and construction activities proceeded smoothly to enable the commencement of mining activities in 1964 and the commissioning of the milling facilities at the end of 1965. Anode copper was first produced in early 1966 which was the first year of full production on the project.

Subsequent History

The design capacity of the mill was attained after only a few months of operation and, due to metallurgical improvements, the milling rate had reached 43.5 kt/d by mid-1968. A mill expansion was completed in 1969, involving the addition of a sixth milling section, designed to raise milling capacity to 49 kt/d. In the ensuing years this capacity was invariably exceeded by margins of well over 1 Mt/a.

In 1977 a further mill expansion was completed which involved the installation of a third primary crusher and two autogenous grinding mills. With this expansion, planned milling capacity was increased to 75 kt/d. After initial design problems in the autogenous mills had been corrected, the design capacity was again exceeded and current capacity stands at 80 kt/d.

The foregoing history of mill expansions could not have taken place without corresponding far-reaching changes in the open-pit operations. These changes are discussed in the following section.

OPEN PIT DESIGN AND MINE PLANNING

Introduction

The original open-pit design envisaged a pit life of 26 years, ore production of 30 kt/d and an overall mining rate of 75 kt/d for the first years of operation. A series of mine expansions associated with the increased milling rates described and/or the need to extend the life of the operation has led to a new termination date in the year 2000, repre-

senting a total pit life span of 35 years. The peak mining rate for the mine plan presently in effect occurred in 1980 and was 350 kt/d. A uniform ore requirement of 80 kt/d of ore is achieved through the life of the plan. At present the cutoff grade is 0.15% copper and the average mill head grade is 0.50% copper.

In addition to copper minerals in the ore, iron in the form of magnetite and phosphate in the form of apatite are present in significant quantities. The amount of titania in the magnetite has an effect on its salability and consequently the ore is subdivided into two streams with ore containing magnetite with a titania content of less than 1.0% reporting to one stream and the balance to another. This separation is initiated at the mining stage and is maintained through the mill. Fortunately, this division coincides with the low- and high-phosphate-bearing ores, the economic portion being associated with the high titania stream.

Palabora's mining lease does not permit the company to recover phosphorus minerals. Under various agreements, which in certain cases allows the mining of claims belonging to FOSKOR, phosphate-bearing tailings from the concentrator and rock from the open pit are delivered to FOSKOR's facilities situated close to the open pit.

Because of the pipelike formation of the ore body, successive pit expansions have had to carry the burden of ever increasing quantities of peripheral waste that necessitate high initial waste: ore stripping ratios. These ratios and, therefore, the peak mining rates will diminish in the latter portion of a mining plan's life, as mining activity enters the ore body fully with depth.

In 1978, based on outlook for copper, it appeared that the then pit design marked the economic limit of open-pit mining. A further expansion (a mean of 116 m radially) was made possible under a new agreement with FOSKOR whereby FOSKOR agreed to make certain financial contributions in exchange for greatly increased deliveries of high-phosphate-bearing material resultant from the expansion.

Mining of this expanded pit (pit 5, Fig. 6), which is still the design in effect, commenced in 1980. The current plan

Fig. 6. Northeastern corner of the pit showing the 1980 extension cut with plant in background.

Table 2. Key Parameters Associated With the Various Major Pit Plans

Pit No.	Designation	Date Commenced	Daily mining rate, kt/d		Pit tonnage, millions of t			Ultimate pit depth, m	Completion year
			Ore	Peak	Ore	Waste	Total		
1	Feasibility Pit	1964	30 000	75 000	286	254	540	366	1991
2	BD-2AM.36	1970	52 500	205 000	471	478	949	467	1990
3	BD 13D	1974	74 000	300 000	655	861	1516	668	1994
4	BD 13E	1978	75 000	290 000	612	780	1392	668	1992
5	100F	1980	80 000	350 000	837	1240	2077	836	2000

requires an average mining rate in excess of 325 kt/d over the period 1980-1987 with sharply reducing mining rates in subsequent years once the major portion of the waste mining has been completed.

It is interesting to note that the original "feasibility pit" of 1963 contained a total of 535 Mt of material. The most recent plan contains over 2.1 Gt or just slightly less than four times the original.

Salient information on the various pit designs are given in Table 2. Graphical representations of achieved and projected pit production levels and limits are as shown in Figs. 7, 8, and 9.

8.2 Mine Planning

The high production rates demanded from a pit of relatively small surface area has made mine planning of a high order absolutely essential to the success of the mining program.

The original ore reserves used for the early mine planning were of a polygonal type and were extremely ponderous to use. In the late 1960s, a cubic block matrix model, eventually to comprise some 650 000 blocks, was adopted to represent the ore body. Each of the ore reserve blocks (15 × 15 m × bench height) may be assigned as many as 31 fields of information. Included in the present model is such information as rock density, copper mineral inventory, copper and accessory mineral grades, blasting restrictions applicable to the particular rock type, and details of the property rights within the mining lease. Coordinate information is also assigned to each block.

The block model is stored on hard disk and is ideally suited to access by computer. Sophisticated evaluation programs are used to determine optimum pit shape and the economics of successively larger incremental expansions to the base pit design. Having established the overall pit design, another suite of specially designed computer programs, which have been upgraded to include interactive graphics features, are used to access the ore reserve data for planning and evaluation of various mining options. This system allows for the development of sequential mine plans as well as providing for updating of mine plans, the rapid evaluation of different cutoff grades, rates of ore exposure, and changes to pit geometry for geotechnical reasons. For example, it is not uncommon for the cutoff grade of the ore to vary for given differing economic conditions and availability of downstream plant throughput capacity. Similarly long-term plans can be quickly adjusted to cater for changes in mining rate to smooth equipment requirements.

Typically, sequential long-term mine plans are developed at quarterly intervals through to end of mine life. These plans then form the framework within which more detailed short-term mine plans and shovel, drill, and blast schedules are produced by pit operations engineers.

As part of the short-term planning process appropriately detailed six-month, monthly, two weekly, and daily plans are developed by the pit planning engineer. A key to the success of short-term planning is the close and interactive relationship which exists between pit planning, production, drill and blast, geology, and survey personnel.

8.3 Pit Slope Design

After a number of years of testing presplit and perimeter blasting techniques, a successful means of controlled blasting was developed in 1978. The method was amenable to a rapid rate of final wall exposure where it is not unusual to require the development of over 2 km of final wall in a single month. It also minimized the amount of blast shatter on final faces and reduced back break on bench crests. As a direct result of the use of this controlled blasting technique, it became possible to introduce double benching, effectively further increasing the available catchment area of the safety berms and thereby making steep wall angles a practical possibility.

Subsequently it was decided to undertake a detailed geotechnical study to determine optimum safe slope angles for the pit, incorporating double benching (Fig. 10). Structural mapping of pit walls was carried out routinely since 1974; however, with the new emphasis on slope stability these efforts were intensified. By 1980 over 32 km of bench face had been mapped in detail and more than 3000 rock samples had been tested for mechanical strength. The results of the study indicated that the competence of the rock mass was such that the possibility of deep-seated failure was remote. Rather, the factor controlling safe slope angles lay in the provision for an adequate catchment area to provide for the localized wedge failures which would occur over the life of the pit. To optimize the pit design variable, slope angles ranging from 40° to 58° were incorporated in the design, dependent on the nature of the wedges present in the wall and the wall orientation. The use of artificial support measures for areas of local weakness and the provision for adequate dewatering of final walls were included as part of the design philosophy.

All of these developments have been incorporated into the latest pit expansion which was commenced in 1980.

The design of the current final pit shell and projection of the various slope angles used in its design are shown in Figs. 11 and 12, respectively.

MINING OPERATION AND ITS EVOLUTION

Original Equipment

The geometry of the deposit and the need to deliver material to multiple destinations combined to make Palabora a conventional hard rock truck and shovel operation. Because Palabora was distant from the sources of supply for its major items of equipment, which were mainly from North America, it was logical to select items which had been well proven in the field.

1966 through 2000

Fig. 7. Achieved and projected mining production levels and limits for life of open pit, showing (A) annual tonnage of total rock mined and ore milled; (B) average annual waste:ore ratio (1.50:1.00 overall, 1966-1999); (C) average annual mill-head copper grade in percent; (D) open-pit copper cutoff grade in percent; and (E) annual tonnage of anode production from mill ore.

Fig. 8. Surface pit limits of major mining plans implemented since 1966. Long axis: pit 1, 1.54 km; pit 5, 1.79 km. Short axis: pit 1, 0.76 km. Ore body limits defined by copper content (assay limits, not lithological or other physical limits).

Fig. 9. East-west cross-sectional view of major pit mining plans with superimposed World Trade Center buildings. Depth below datum elevation: pit 1, 366 m (27 benches); pit 5, 805 m (56 benches).

Fig. 10. Double benches on the south side of the pit.

In addition, shovel choice was governed by a number of factors. First, two ore types would be mined separately and wide daily grade fluctuations were to be avoided. Second, the high initial cutoff grade (0.40% Cu), coupled with a need for rigid waste segregation, indicated a need for small shovels for selectivity purposes.

On the basis of these criteria, initial equipment chosen consisted of 229 mm diam, well tried down-the-hole hammer drills, single rear axle mechanical drive dump trucks of 59 t capacity, and a shovel fleet of eight units, consisting of five

electrically powered P&H 1600 shovels, one electrically powered P&H 2100 B shovel, and two diesel-powered P&H 1400 shovels.

Subsequent Equipment

Successive pit expansions created opportunities for rationalization and modernization of equipment and Tables 3 and 4 show the changes in the truck, drill, and shovel fleets over the years. Today, electric power has totally replaced diesel fuel in drilling and loading and has become the major energy component of the hauling process.

Increasing peak mining rates resulting from successive pit expansions has made it mandatory to purchase larger equipment capable of higher productivity in order to avoid congestion in the relatively small pit area. The larger units of drilling, loading, and hauling equipment have also had the effect of containing unit operating costs.

As may be noted from Table 4, the average daily production level per shovel unit increased from 9.4 kt in 1966 to 34.3 kt in 1986, clearly illustrating the trend toward a relatively smaller number of larger machines. This same trend is apparent for the haul truck fleet.

From the onset of operations the philosophy has been to minimize the numbers of equipment deployed by maximizing equipment utilization. To this end maintenance availabilities have been an area of particular attention and over the years the major fleets have enjoyed mechanical availabilities in the 90% range. To keep up with the greatly expanded equipment fleets resulting from the 1980 expansion, a fully computerized on-line system to monitor operating performances, schedule maintenance, and track spares inventory for all open pit equipment was introduced in 1982. Over the past five years it has shown substantial benefits in improved availability of equipment and savings in consumption of spares.

Fig. 11. Ultimate pit design.

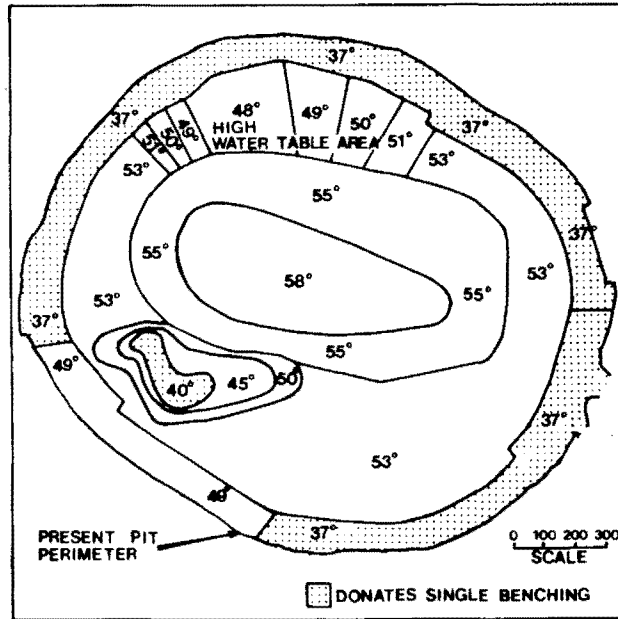

Fig. 12. A plan view showing the inter-ramp slope angles used in the Palabora pit slope design.

Drilling and Blasting

Drilling is accomplished by a fleet of eight Gardner Denver model 120 rotary blasthole drills. These units are equipped with 28-m masts, capable of single pass drilling on Palabora's 15.2-m bench height. Currently a 311-mm hole size is used for all blastholes. Four distinct bit types are used for drilling the various formations. These are "sulfide," "fenite," "dike," and "sulfide dike contact."

Drill patterns are varied depending on the particular area of the pit and material being blasted. Typical drill patterns

range from 6.7×7.6 m to 7.0×8.1 m. Hole patterns are staggered and normally 2.4 m of subdrill is used for each hole.

In the central core of transgressive carbonatite, grade values showed little fluctuation and five row shots are allowed. Elsewhere in the ore body, grade variations are much more pronounced and three row shots are the norm with the objective of minimizing dilution. In pure waste areas no limits are placed on the numbers of rows shot.

Primary blasting is carried out using emulsion explosives made under a license agreement with Ireco. Three grades of emulsion with varying aluminum content can be produced. A typical blasthole will be loaded with 1000 kg of emulsion consisting of 350 kg of aluminized emulsion bottom load and the balance being made up of zero percent aluminum content emulsion. Each hole is stemmed with approximately 5.8 m of drill cuttings. Patterns are shot on the long axis with 40 millisecond delays between rows.

Trolley Assistance

Rock haulage has become the single most expensive process in the entire mine and plant operation. It accounted for only 33% of the total mine and plant operating cost in 1975, but was made more expensive mainly by the energy crisis of the 1970s; by 1981 it was responsible for 57% of the operating cost; In the years 1978 to 1980 alone the price of diesel fuel in South Africa increased by over 320%. This, combined with the increase in mining rate as a result of the 1980 pit expansion, was a pressing reason for finding an alternative or less expensive mode of rock haulage. The consumer cost of electrical power in South Africa is among the lowest in the world and it was accepted that its escalation in real terms would be appreciably less than that of diesel fuel.

Studies undertaken to investigate alternative or complementary means of material handling indicated that the use of electric trolley assistance for the haul truck fleet would offer the fastest and most attractive return to the company. In 1981, after less than two years of development work, Palabora introduced a system of trolley assistance for the

haul truck fleet. Initially a total of some 2.7 km of adverse 8% haul ramp was equipped for trolley assist.

Under trolley assist the haul truck collects electric power from the fixed overhead conductor system. The power is supplied directly to the electric motors of the haul truck located in the rear wheel hubs. This eliminates the need for the truck engine to drive the truck alternator to generate its own electricity. Fuel consumption for a 154-t capacity truck hauling up an 8% adverse grade is 24 L/km diesel fuel. That same truck on trolley assist uses approximately 0.5 L diesel fuel per kilometer of travel. In 1982, the first full year of trolley-assisted operation, diesel fuel savings amounted to 17 mL. By 1986 these savings increased to 37 mL (Fig. 13). Energy cost savings from the use of lower cost electrical energy as a result of trolley assistance amounted to R12.6 million in the same year.

As a result of increased vehicle speed while on trolley, significant productivity improvements have been achieved. In 1986 this higher speed and consequently improved truck cycle time equated to a reduction in required truck fleet of seven 154-t capacity units.

Because the truck engine does not work as hard while on trolley, the engine lasts longer. Engine life has over the past six years more than doubled as a direct result of trolley assistance. Wheel motor armature life has also improved as a result of the shorter time spent on grade. On the basis of calculation, it is estimated that armature life is presently 160% greater than would have been the case without trolley assistance. Although an item of initial concern, experience has shown that there is no net reduction in tire life resulting from the use of trolley assist.

Currently, 7.7 km of trolley-assisted ramps (Fig. 14) are in use at the Palabora pit. With the significant energy cost savings realized by the system and the other benefits which more than double the savings, there is every incentive to

advance successive planned phases of the system as the pit deepens.

Haul Truck Control

With 14 different material classifications and a corresponding complex haul route system, the potential to improve efficiency by computer-aided control of trucks and related production equipment was recognized early and Palabora installed the first automatic computer-aided truck dispatch-

Fig. 13. Diesel savings as a result of trolley assist.

Fig. 14. Hauling using trolley assist.

ing system in 1972. This system, although simple, was effective and achieved an immediate increase in fleet utilization. The system worked well and enjoyed a high operating availability.

Recently, however, technology had developed sufficiently that it became feasible to introduce a more sophisticated truck dispatching system, which integrated all aspects of open pit production. In 1985 the old dispatching system was replaced by a customized Modular Mining dispatch system. With this system each piece of production equipment, shovel, trucks, crushers, is equipped with its own microprocessor (Fig. 15) which communicates with a central VAX 780 computer by radio. On the basis of information received, the central computer is able to determine all vital parameters such as shovel loading rates, crusher digestion rates, and

hauling rates, etc. By a network of key points along haul routes, the system is able to track haul truck traffic throughout the haul cycle. In addition, equipment operators provide further information through purpose built terminals located conveniently in each operator's cab. The central computer is able to use linear programming techniques to optimize equipment assignments and consequently improve productivity.

Within a few months of commissioning the new system had proven itself to the extent that it was possible to reduce the truck fleet by five units. The productivity improvement was found to be 7% greater than the previous arrangement. In addition, the system offers numerous other advantages, including the ability to evaluate production performance, more accurate production records, and a complete record of activities of all major mining equipment.

In-Pit Crushing and Conveying

Trolley-assisted haulage was chosen in preference to alternative materials handling methods in the early 1980s. However, the possibility of crushing and conveying remained under study and in 1985 a concept involving a simple crusher and conveying system with the crusher positioned on the final wall of the pit emerged as a cost-effective solution.

The in-pit crushing system was looked at in a context of long-term ore haulage requirements. The study showed that the in-pit conveying system would be economically and practically more attractive if it could be extended periodically to follow pit depth advances so as to eventually cater for a changeover to underground mining.

The current in-pit crushing and conveying concept achieves these goals in three distinct phases, each of which will be required to stand successively on its own economic merits.

Phase 1 of the system is currently under construction and consists of a 60 × 89-in. (152 × 226-cm) gyratory crusher conventionally installed below a flat area at bench 28 (Fig. 16), some 300 vertical m below the pit rim. Ore from the production benches will be trucked to the crusher via the trolley-assisted haul ramps. The crushed ore will be fed to a 1.1-km long 1800-mm wide conveyor belt up an inclined (15.5°) tunnel. After exiting the tunnel at surface,

Fig. 15. Dispatch panel mounted in a haul truck cab.

Fig. 16. In-pit crusher excavation on bench 28.

the material will be conveyed by a series of shorter belts and deposited on the existing coarse ore stockpiles. Two of the three existing surface crushers will remain functional and on standby as backup to the new in-pit unit and also to process low-grade surface stockpiles as required by the mine plan.

Phase 1 will be operational early in 1988 and could remain in use for the duration of the pit life but is currently designed to be in operation for 6.5 years during which time an extension conveyor tunnel will be developed from the phase 1 crusher chamber behind the pit wall to the phase 2 station at bench 44, a further 250 m vertical lower down.

The phase 3 crusher will in turn be located 60 m below the conventional pit bottom at bench 58 and will be housed in an underground chamber behind the pit walls. It will connect to the phase 1 transfer station by a dogleg conveyor tunnel that bypasses the lower leg of the phase 2 conveyor, which becomes redundant. The total vertical lift to surface would be around 780 m through the three conveyor sections.

The operating cost of the phase 1 crusher conveyor system will be significantly below the present trolley-assisted haulage cost. In 1988 terms, the cost of conveying the material by a conveyor from bench 28 to the surface is estimated at R0.19t as compared to the cost of hauling which would amount to

R0.82t for the same lift. The phase 1 conveyor will allow the truck fleet to be reduced by over 14 units.

A diagram of the three phases of the crushing and conveying system are shown in Fig. 18.

Support Equipment

As is usual in this type of operation, there is a very comprehensive fleet of support equipment at Palabora. The major items are listed in Table 5.

Equipment Performance

Before quoting performance figures it is necessary to understand the basis for calculating the statistics. The central formulae in use are: mechanical availability (MA) percent is defined as:

$$\frac{(\text{used time} + \text{operational delay time}) \times 100}{(\text{Total time} - \text{standby})}$$

or alternatively

$$\frac{\text{time available for operation} - \text{standby} \times 100}{(\text{Total time} - \text{standby})}$$

where used time is the time equipment is operated, operational delay time is time that equipment is not used due to being delayed for operational reasons, total time is total calendar time when mining operations are being carried out, and standby is time when equipment is not scheduled to operate but mining operations are in progress.

Mining Organization and Manpower

Of the present employee strength of approximately 3900, one-quarter is of European descent. In the commissioning and the early operational years of Palabora, an exodus of mining personnel from the Zambian Copper Belt provided Palabora with a significant portion of its total staff complement. They were skilled in almost every facet of copper mining and metallurgical operations. The balance of the skilled white labor force was obtained from the long-established mining industry of South Africa. Heavy reliance was placed on overseas specialist assistance, especially from North America, and although this has now diminished, Palabora still utilizes overseas expertise in the form of visiting consultants.

TOTAL	744	497	1 241	745	493	1 238	

* Ops = Operations
* Maint = Maintenance

Fig. 18. Organization of the mining department.

Palabora managed to establish a relatively efficient and stable labor force from the very onset of operations. Locally recruited people have adapted to the modern industrial environment through sustained training in the classroom and "on-the-job." Turnover has been minimized by the adoption of a policy, unique at the time in South Africa, of accommodating all black employees with their families as close to the mine as possible. Supporting social services, such as

schooling, recreational facilities, hospitals, and a technical training school, have been provided progressively over the years. As a result, a remarkably stable black labor force has been achieved, in which levels of technical and operational proficiency have steadily increased. Judged by any standards, an annual turnover maintained at less than 6% of those employed must be considered exemplary.

The company boasts of a fully integrated salary structure and equal conditions of employment for all employees. Employment and promotional opportunities are provided on a basis of merit and experience only.

Fig. 19 shows the organizational structure of the mining division and 1986 authorized manning levels. In 1986 an open pit productivity of 257.9 t per man shift was achieved. This figure takes into account shifts operated by nonpit personnel such as surveyors, geologists, and other members of the mine engineering department.

CONCLUSION

The past 20 years have seen Palabora evolve to take advantage of new technology and the economies of greater throughput to maintain its position as one of the world's low-cost copper producers. A measure of this is the fact that despite the ruling depressed price levels for copper in 1986, Palabora managed to achieve its highest level of profitability.

Much obviously depends on the future price of copper. However, Palabora is in a comparatively strong position whatever situation arises. Benefits from the many cost-savings measures introduced over the years will continue to accrue to the company but Palabora's real strength in the future continues to lie in the training and organization of its

INTRODUCTION

One of the large copper properties in the world today is The Phelps Dodge Morenci, Inc. operation located near the confluence of the San Francisco and Gila rivers in eastern Arizona.

The Morenci operation encompasses two operating open pit mines, two concentrators, extensive dump leaching, two copper precipitation plants, a large solvent extraction/electrowinning facility including three separate solvent extraction circuits, two power plants, shops and maintenance facilities necessary to support those operations, and a townsite where most of the employees live. It is the largest of Phelps Dodge Corp.'s copper mining and processing complexes, normally producing about 50% of the company's new copper output.

Early History

First discovery of mineralization in the district was recorded in 1864. The earliest production of any consequence occurred in 1872 when copper oxide ore of very high grade was mined and processed by direct smelting methods. Some of that early copper production was hauled overland by mule- and oxen-train to Kansas City, Missouri.

By the 1880s, a number of companies were operating in the district. These included the Detroit Copper Mining Co., the Arizona Copper Co., the Longfellow Copper Co., the Shannon Copper Co., and several smaller companies.

Phelps Dodge's entry into the region, and in fact into copper mining, occurred in 1881 when it acquired partial ownership of Detroit Copper Mining Co.

Ownership in the district was gradually consolidated until only the Detroit Copper Mining Co. and the Arizona Copper Co. remained. After 1897 Phelps Dodge assumed full ownership of the Detroit Copper Mining Co. In 1921, Phelps Dodge purchased the Arizona Copper Co. to become sole operator in the district.

With the exception of some surface *glory holing*, all mining prior to 1932 was by underground methods. Both high-grade copper oxide and copper sulfide veins were mined. As mining progressed, exploratory drilling revealed a very large low-grade deposit of disseminated chalcocite, called the Clay ore body, in porphyry host rock.

Initiation of the Morenci Open Pit Copper Mine

Pioneer exploratory work on the Clay ore body by Arizona Copper Co. and later by Phelps Dodge Corp., revealed that the porphyry copper deposit lay beneath 60 to 150 m (200 to 500 ft) of leached capping. Phelps Dodge began a systematic drilling program on the Clay ore body in 1928 to confirm and augment information gained earlier by Arizona Copper and Detroit Copper companies. The drilling, which continued until November 1930, confirmed the existence of more than 181 Mt (200 million st) of material averaging slightly more than 1% copper.

One of the key questions to be resolved was whether to mine the ore by underground block caving or by the open pit method. In considering the choice the following items were studied:

Minimum dilution of the ore, maximum recovery of the ore, low maintenance costs, favorable production costs, production flexibility, uniform ore production and stripping rates, availability of space to locate waste and leach dumps, good physical layout for haulage systems, minimum pre-ore stripping, 209 Mt (230 million st) of ore at 1.06% Cu, and a waste to ore ratio of 1:1.

After a year of investigation, it was determined that the open pit mining method could recover about 10% more copper, reduce final average mining costs by more than 30%, and could ultimately yield from 20 to 25% greater profits.

Development of the mine, however, was only one phase of the large and costly enterprise. The old No. 6 Concentrator and its various units at Morenci were inadequate to process the huge tonnage that the new mine was designed to produce and the old facilities were not advantageously located. Further evaluation indicated that it would not be economically feasible to enlarge and modernize these existing facilities.

A decision was made to construct a new infrastructure—crushing plant, mill, smelter, power plant, and auxiliary facilities necessary for a major mining operation.

The site selected for the crushing plant, mill, smelter, and other units would lie almost halfway between the towns of Morenci and Clifton and would allow the ore to be delivered by favorable haul from the mine over a significant portion of the mine's life. By the time the preliminary study was completed, the United States had entered the Great Depression and development was suspended pending improvement in the economic climate.

In 1937, encouraged by the economic outlook, Phelps Dodge reactivated the Morenci Project. In June, the company made a public offering of \$20,285,000 of 15-year convertible 3-1/2% debentures. They soon were sold and work on the mine and related facilities began. The balance of the total estimated cost of \$35 million came from corporate earnings as the work progressed.

The size, quantity, and cost of the equipment and facilities required for a task of such magnitude taxed the imagination. The new mine at Morenci was to become a huge, complex, and thoroughly mechanized industrial operation.

To provide for the great increase in personnel that the new operation required, Phelps Dodge laid out a new townsite. The company built more than 300 housing units that would be rented to employees at nominal rates. The project also included the expansion of recreation and school facilities and the construction of a new hospital with the most modern equipment.

In 1937, the pre-ore stripping of 44 Mt (49 million st) of overburden commenced at the Morenci mine with shovels and trucks developing 15-m (50-ft) high mining benches and railroad access. The trains were added later to handle the movement of large tonnages of material over long distances including ore deliveries to the Morenci primary crusher. The physical features of the topography permitted the installation of the main line haulage tracks outside final pit limits and also permitted the favorable downhill movement for an estimated 85% of the material to be handled.

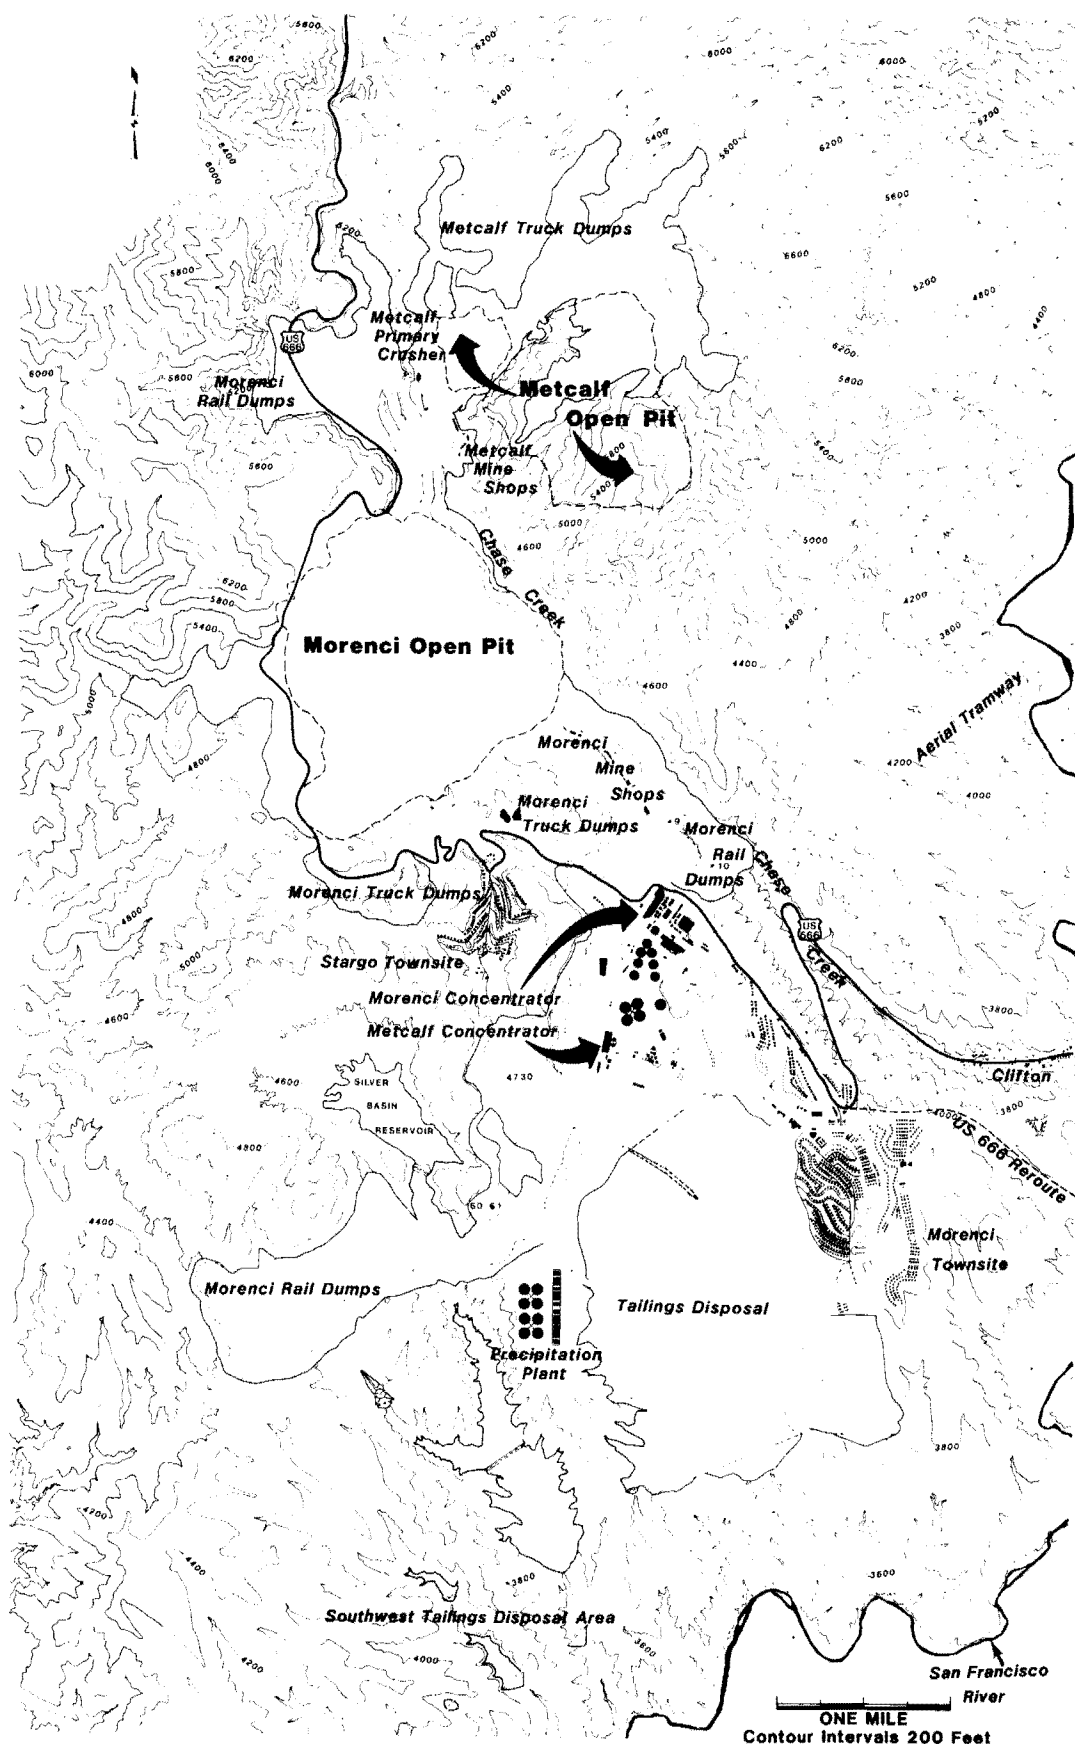

Fig. 1. Map of the Morenci district.

Copper concentration studies were resumed in 1938 following a six-year hiatus to test various types of equipment and to develop a final concentrator flowsheet. Ground was broken for the new concentrator and smelter in 1939. The first copper anode was poured on April 26, 1942.

Wartime Expansion

The Morenci operation was designed to process 22.7 kt (25,000 st) of copper ore per day. However, in 1941 the nation was facing international war, and the federal government urgently requested Phelps Dodge to expand the Morenci Project by 80%, to a capacity of 41 kt (45,000 st) of copper ore per day. Responding to this request, the company designed, constructed, and completed a major expansion project in slightly more than two years.

By the close of World War II, Phelps Dodge had spent approximately \$42 million on the Morenci project and the federal government's Defense Plant Corp. had provided an additional \$26 million. The facilities provided by the US government were sold to Phelps Dodge after the war ended.

The Postwar Years

Additions and improvements raised the capacity of the Morenci concentrator to its present level 59 kt (65,000 st) of copper ore per day with a corresponding increase in mining rates.

Major improvements in recent years have included construction of the largest solvent extraction/electrowinning complex in the United States to recover copper leached from mine dumps. The mine dumps contain copper-bearing material with grades too low for processing through the concentrator.

Since the initiation of the Morenci mine in 1937, about 2.0 Gt (2.2 billion st) of rock have been moved, of which about 690 Mt (760 million st) were ore averaging 0.86% copper. Approximately 530 Mt (584 million st) of material remain to be mined under current plans. The present Morenci pit covers some 595 ha (1,470 acres), measuring about 2.9 km (1.8 miles) north to south and 2.4 km (1.5 miles) east to west. Mining, which began at 1691 m (5550 ft) above sea level, has continued down to the 1219 m (4000 ft) level. Current mine plans indicate that the final bottom of the pit will be at the 1021 m (3350 ft) elevation.

Metcalf, A Second Open Pit in the Morenci Ore Body

In 1970, development of the nearby Metcalf mine was initiated to replace, insofar as overall company production is concerned, the production lost when the open pit and underground mining operations ceased at Bisbee, Arizona, in 1974 and 1975. The Metcalf development, operated as part of the Morenci Branch, also required construction of a new concentrator built southwest of the Morenci concentrator.

The Metcalf copper deposit is an upfaulted portion of the Morenci ore body and is located a short distance north and on the opposite side of Chase Creek from the Morenci open pit mine. Development of the Metcalf area began in 1870 when Robert Metcalf struck a rich copper oxide vein upstream from Clifton. Metcalf returned to the area about two years later and located the Longfellow claim and mine. The mine was acquired by the Lezinsky brothers, then by the Arizona Copper Co., and finally by Phelps Dodge in 1921 as part of the acquisition of the Clay ore body.

Exploration drilling at Metcalf began in the 1960s and in 1969 the company announced plans to develop the Metcalf mine. By December, 1974, the Metcalf project was substantially completed—at a cost of almost \$200 million.

Due to the extremely rugged terrain at the mine site, it was necessary to locate the concentrator for Metcalf ore adjacent to the Morenci concentrating and smelting complex. However, the primary crusher was located near the mine. After the Metcalf ore is crushed using a 1.52 m (60 in.) gyratory crusher at the mine, the ore was hauled approximately 8 km (5 miles) by rail to the concentrator. The facility was designed to handle 27 kt (30,000 st) of ore per day, although it has a proven capacity of 41 kt (45,000 st) of ore per day.

Pre-ore stripping resulted in the removal of 68.6 Mt (75.6 million st) of overburden. To maintain ore development, a stripping ratio of 2.5:1 was required. However, that ratio was not achieved for several years following startup due to economic constraints. Since production began in 1974, 39 Mt (43 million st) of copper ore averaging 0.76% copper have been mined. All material mined since stripping began totals about 220 Mt (242 million st).

During the years 1977 through 1980, a very substantial portion of the Metcalf concentrator ore supply was provided from the Morenci open pit. Early in 1981 the Metcalf open pit was shut down, the entire 100 kt/d (110,000 stpd) of ore production for the two concentrators (Morenci and Metcalf) was shifted to the Morenci mine along with the mining equipment to take advantage of the lower waste-to-ore ratios and slightly higher ore grade. There remains about 0.9 Gt (1.0 billion st) of material to be mined at Metcalf.

Consolidation of Potential Mining Areas at Morenci

Phelps Dodge completed the consolidation of all potentially minable copper properties in the Morenci district in 1981. This was accomplished through purchase of the Western Copper property for \$10 million. The property, acquired from Hanna Mining Co., consists of 81 patented claims covering 754 ha (1862 acres). The property is located on the east side of Chase Creek at the eastern limit of the Morenci mine and at the southern limit of the Metcalf mine. It is part of the Morenci copper mineralization, as is the Metcalf deposit. Portions of the Western Copper property are included in the final pit limits of both the Morenci and Metcalf mines.

The relatively low elevation of the Western Copper property makes it ideally suited for use as a waste disposal area for both the Metcalf and Morenci mines. Substantial reductions in haulage costs are anticipated because of shorter distances and favorable grade compared to disposal of Metcalf waste on dumps located at higher elevations north and east of the Metcalf mine.

MINES DEVELOPMENT

As previously indicated, the construction of a major copper mining complex in a remote setting requires a great amount of auxiliary development. In addition to direct mine and plant structures and equipment, a significant amount of pre-mine fact gathering, planning, and design, as well as support facility logistics development are required.

Water Supply Development

Because of the increased copper production brought on by the expansion of the Morenci mine and concentrator in the 1940s, there also was a corresponding need for additional water. In order to meet this water demand, innovative arrangements were developed to import the majority of the required water from various sources outside the Morenci district. To accomplish this, several dams, pumping plants, pipelines, powerlines, and support facilities were constructed, as shown in Fig. 2.

Fig. 2. Map of Arizona showing the location of Morenci's water development system.

In 1947 Horseshoe Dam was the first constructed retention structure for the collection of surface runoff, followed by Jacques Dam in 1954 and Blue Ridge Dam in 1965. Then, through various agreements and water exchanges, Phelps Dodge was permitted to divert water from the Black River, 43 km (27 miles) northwest of Morenci, and transfer it into Eagle Creek. The water diverted from the Black River flows south to the lower reaches of Eagle Creek where it is pumped 9.6 km (6 miles) to Morenci. A well field in the upper Eagle Creek area also has been developed to augment surface water sources with groundwater as necessary.

Water use by the entire Morenci Branch operations consists of 30.837 Mm³ (25,000 acre-ft) per year of which 617 000 m³ (500 acre-ft) per year are used by the mines for dust control, cleaning of equipment, change room services, and other minor uses. Water is pumped to head tanks located near the top of the mine and then gravity fed to the place of use. Rubber hose of 38 mm (1.5 in) diameter is used to furnish water to the open pit mining faces. This provides a flexible, inexpensive transport system.

Utilities

Electrical power is distributed to the Morenci mine through two 46 kV power transmission lines. This power line feeds a 15 MVA substation in the bottom of the Morenci pit. Voltage is transformed down from 46 kV to 4160 V and is distributed from the substation through radial power lines placed perpendicular to the mining faces. Switchhouses are located at the bottom of selected wooden power poles in active mining areas from which insulated electrical cable provides power to the mining equipment.

One of the 46 kV power lines extends past the Morenci substation to the Metcalf mine. This voltage is then transformed at two 5 MVA substations to feed the shops, the Metcalf solvent extraction plant, and primary crusher. The

total connected load in the Morenci and Metcalf mines is about 25 megawatts.

Natural gas is provided to the Reduction Works area through two main pipelines: a 152 mm (6 in.) and 203 mm (8 in.) line, both at 4100 kPa (600 psi). The natural gas then is redistributed to the Morenci mine shops through a 102 mm (4 in.) feeder line at 621 kPa (90 psi). The annual mine consumption is about 708 m³ (25,000 ft³). Propane, delivered by truck, is used at the Metcalf offices and shop area, since an active mining area is located between the Morenci mine shops and the Metcalf mine shops.

Compressed air at about 621 kPa (90 psi) is provided to the Morenci mine shop area from the Morenci power plant through a 152 mm (6 in.) pipeline. Compressed air at about 758 kPa (110 psi) is provided to the Metcalf shop area by two stationary 10 m³/min (355 cfm) air compressors located at the Metcalf shop area and distributed through a 102 mm (4 in.) pipeline.

Fire protection for the mine complex is provided through the use of fire hydrants located near principal mine buildings, fire extinguishers on mobile equipment, and water trucks equipped with fire hoses or water cannons. A volunteer fire department trained to fight industrial fires is also available.

Mine Planning and Mine Engineering

Before development of Morenci/Metcalf mines could begin, it was essential to determine the location of the copper ore body, thickness of the overburden, grade of the ore, type and character of the rock to be milled, and location of dumping areas. This was accomplished by drilling a portion of the 1450 vertical diamond drill and churn drill holes now in the data base, as well as extensive sampling and some diamond drilling from the underground workings.

For the surface drilling, 122-m (400-ft) grid with a center hole in each 122-m (400-ft) square initially was used. Later, this was modified to eliminate the center holes. The ore body at the Morenci/Metcalf mines is a large porphyry copper deposit. The dominant rock types that host ore are monzonite porphyry, granite, and granite porphyry, with minor amounts of limestone, shale, and quartzite.

Sulfide ore mineralization is typified by supergene chalcocite and covellite replacing pyrite, chalcopyrite, and minor amounts of bornite. This sulfide mineralization occurs in veins, veinlets, microveinlets, and disseminations.

Oxide ore minerals present within the mining limits include azurite, malachite, tenorite, brochantite, chrysocolla, and cuprite. Minor amounts of native copper are encountered locally. Minor amounts of gold, silver, and molybdenite also are included in the ore and are collected with the copper sulfides in the concentrating process.

The material in the minable reserve is classified into three separate materials: ore, leach, and waste. Material classifications by contained copper are as follows:

Ore	≥ 0.40% Cu
Leach	≥ 0.20% Cu ≤ 0.39% Cu
Waste	≤ 0.19% Cu

Material that is above 0.40% copper, but exhibits more than half of the contained copper as oxides, is reclassified as leach and handled accordingly.

In evaluating the drilling results, the area of influence of each drill hole was determined by using the polygonal technique. Drill hole assays averaged in 15-m (50-ft) vertical increments corresponding to the mining levels were used in assigning polygonal block grades for each drill hole. An average density of 0.354 m³/t (12.5 ft³/st) was used to cal-

culate tonnages included within the polygonal blocks. In the absence of geological information, drill holes that ended in ore were not projected downward. Drill holes that ended in non-ore material were projected downward as waste to determine a boundary for adjacent holes.

Final copper reserve mining slopes are set at 51° based on geological evidence, rock strength characteristics, shape of the banks, and length of the slope. Initially, the Morenci pit mining limits were projected to be on a 45° overall slope, but were changed to a 37° overall slope, and later to a 51° overall slope.

The final reserve slopes are calculated using an economic model based on the value of the copper recovered from a block of material and the amount of overburden removal that the specified value can support.

A mine planning staff is located at Morenci to develop annual and long-term mine plans, as well as to review district copper ore reserves, and to prepare feasibility studies for improved mining methods. Presently the polygon method of reserve calculation is under review and efforts are being made to reevaluate the district's mining reserves through computer-generated block modeling and geostatistics. Other feasibility studies focus on improving mining efficiencies and alternatives to the conventional haulage methods.

The inter ramp slope for final mining limits is 51° with a uniform bench height of 15 m (50 ft) and a working bench width of 30 to 61 m (150 to 200 ft) in most areas. Because of the topography at the Metcalf mine, only truck haulage is used, while the Morenci mine uses both truck and rail haulage. All mine trackage is standard 1435-mm (56.5-in.) gage. The maximum available degree of curvature for main line track is 12°. The main line is constructed of 60-kg (133-lb) rail and normally is located outside pit limits or placed in a semipermanent location. It is a heavily traveled route and therefore consists of double track: one for the loaded trains and the other for empty trains.

The main truck haulage system is designed so that the maximum ramp grade is 10% and ramp width is 30 m (100 ft). This 30-m (100-ft) width allows for large berms on each side of the ramp as well as a drainage ditch. Runaway truck ramps and crash berms built of reverberatory furnace slag are provided for downhill hauls. The minimum radius of curvature for the main haulage road is 61 m (200 ft).

Internal truck ramps are used where necessary and can be narrower than main ramps. Dump loads are designed to be on an adverse grade of 2 to 3% to allow for settlement and to limit the possibility of a truck rolling backwards through the dump berm.

Equipment Selection

The decision regarding type of haulage equipment was based on the following factors: Topography of the area, tonnage to be removed, speed and distance that material must be moved, and overall economics.

The selection of rail haulage equipment was based on the layout of the final track haulage system. To determine the final layout, the maximum safe grade and the size of the train first had to be ascertained.

The train size also had to be flexible enough to meet the varying operating conditions with the maximum car size. Maximum grade was determined to be 4% with a most efficient train size being eight 30.6-m³ (40-yd³) self-dumping side dump cars. Because of the interchangeability and the need to facilitate train dispatching, the same type and size cars were used both for copper ore deliveries to the primary

crusher and for waste and leach material deliveries to the mine dumps.

In the original selection of the locomotive power to be used, serious consideration was given to total electrification of the rail haulage system, but because of frequent changing of the bench track as well as narrow mining benches and heavy blasting, this concept was abandoned. The decision thus was made to use an overhead trolley electrification system only on the main line track system in combination with diesel-electric and battery-electric locomotives for bench and dump track.

Plans for a track extension in 1955 called for the electrification of an additional 8 km (5 miles) of main track. However, due to the high cost of such a venture and improvements over the previous two decades in diesel-electric locomotives, all trolley electric locomotives were replaced with 1306-kW (1750-hp) diesel-electric locomotives. These larger locomotives also were capable of improving efficiency by pulling longer trains.

The present fleet of locomotives consists of 3 895-kW (1200-hp), 13 1306-kW (1750-hp), 2 1343-kW (1800-hp) and 12 1492-kW (2000-hp) diesel-electric locomotives. The present railroad car fleet consists of 200 32.9-m³ (43-yd³) side dump cars, and 53 90-t (100-st) bottom dump cars used only for ore deliveries from the Metcalf primary crusher to the Metcalf concentrator.

Although the Morenci open pit has historically been a rail haulage mine, truck haulage has become increasingly important over the years. The decision to use trucks in the preliminary stripping operations was based on the need to prepare the mine for rail haulage and the success of truck haulage in other large-scale excavations.

Initially, a fleet of 18 17.2-m³ (22.5-yd³) trucks was used to open new levels, to remove overburden from the upper benches and to build railroad access. The fleet in 1970 was upgraded to 47 90-t (100-st) trucks and in the 80s, the old truck fleet was phased out and replaced with 28 154-t (170-st) trucks. Trucks in the Morenci mine now are used for all direct production from the active mining faces while rail is used to transfer ore to the Morenci and Metcalf concentrators.

The selection of loading equipment was based on the following factors: loading rate, size and type of material being loaded, haulage unit being loaded, and life of the operation.

Initially 3.4-m³ (4.5-yd³) electric shovels were purchased for mine development. These shovels were much more efficient and dependable than earlier models and could load the large tonnages required on a daily basis. They also were compatible with the rail and truck haulage units. Shovel equipment life coincided with the expected mine life of 30 years. As the mine developed, shovels were upgraded to larger units. The shovel fleet currently consists of six 11.5-m³ (15-yd³), and six 16.8-m³ (22-yd³) electric shovels. In addition, two 9.2-m³ (12-yd³) rubber-tired front-end loaders are being used as backup production units or for special projects.

Initially, the selection of drilling equipment was based on the following factors: tonnage to be broken per day, size and depth of hole to be drilled, and type of material being drilled.

The large electric churn drill was selected at Morenci because its drilling rate and hole size would allow breakage of a maximum amount of material.

In 1940, all the primary drilling was performed by 12 electric churn drills using 229-mm (9-in.) diameter bits. Blast holes were drilled from 2.4 to 3 m (8 to 10 ft) below grade.

Drill bits were reconditioned by a mechanical shaper and hardened for reuse. In 1956, a portion of the primary drilling was performed by large rotary drills capable of developing 311-mm (12- $\frac{1}{4}$ -in.) diameter blast holes. The rotary drill used tricone bits and 10-m (33-ft) long steel sections. Two steel changes were required per hole. The present primary drill fleet consists of 10 rotary drills: 6 electric and 4 diesel-electric. The diesel-electric drills were used for the early development of the Metcalf mine, two of which have been converted to electric drills. Single pass drilling now is available with the larger drills as well as variable hole sizes ranging from 229 to 381 mm (9 to 15 in.) in diameter.

DESCRIPTION OF OPERATIONS—MORENCI MINE

Breaking Ground

In the Morenci pit, there are certain operating conditions that determine the pattern of blast holes and the powder loading ratios. Drilling access must be maintained and material must be available at each shovel on a continuous basis. To accommodate these constraints, hard toes and high bottoms resulting from unbroken rock, must be avoided.

Drilling and blasting practices in the Morenci open pit have undergone a slow evolution. Initially, 15-m (50-ft) benches were established using 229-mm (9-in.) churn drilled blast holes averaging 17.6 to 18.2 m (58 to 60 ft) in depth. Also, there was a tendency to lighten the burden on the holes in hard ground by decreasing the distance between holes and by shortening the length of the toe. This practice broke the toe well, although it resulted in poor fragmentation in the upper part of the bank. It also yielded a low tonnage per vertical foot of blast hole.

Later, it was found that the heavier the burden without overloading, the better the resultant fracturing. Currently, most blast hole drilling uses 311-mm (12 $\frac{1}{4}$ -in.) diameter rotary bits.

A small amount of secondary drilling is accomplished with air drills equipped with 64-mm (2 $\frac{1}{2}$ -in.) button carbide bits.

During 1987, rotary drill blasts accounted for 70.7 Mt (77.9 million st) of broken ground in the Morenci pit and involved 402 km (1.32 million ft) of drilling. This resulted in 176 t of broken rock per meter (59 st per ft) of blasthole.

Throughout the years as the types of available explosives changed, the patterns and loading ratios also have varied. In the early days of the mine, gelatin dynamite was used. This was followed by bagged ANFO beginning in 1960. In the early 1970s, bulk, prilled ammonium nitrate was used and in 1980, a mixture of ammonium nitrate and aluminum was introduced.

Currently, ammonium nitrate and fuel oil account for about 50% of the explosive utilized in primary bank blasts, although aluminized ANFO in a 10% mixture occasionally is used. An increasing number of wet holes have been encountered that cannot be dewatered, sleeved, and blasted with ANFO. Consequently, such holes are loaded with a slurry form of ANFO.

Trucks outfitted with special compartments are used for loading the ANFO into blast holes. Ammonium nitrate prills, fuel oil, and flaked or granulated aluminum are augered or pumped separately from compartments to a nozzle where they are mixed with the other ingredients while being injected into the hole. Each hole is single primed with an in-the-hole delay cap in a 0.45-kg ($\frac{1}{2}$ -lb) cast TNT booster hung on a 20-grain downline. Individual holes are tied to a 25-grain

trunkline, which is delayed on the surface between rows when a multiple row pattern is used. Slag, gravel, or drill hole cuttings scraped in with a backhoe serve as the stemming material. All blasts are initiated with an electric blasting cap by the blasting foreman. Typically, six benches are guarded against entry during a blast: one above the drill hole collars, the bench being blasted, and four below.

Typical powder factors vary among the different rock types encountered in the Morenci pit; however, most average approximately 5.0 t broken per kg of explosive (2.5 st broken per lb, etc.).

Although the production work schedule is a 24-hr-per-day continuous operation, the drilling and blasting crews work a 40-hr week, seven days per week schedule. Drilling is conducted on a three-shift rotation and all blasting is done on day shift. Each drill shift will result in approximately 90 kt (100,000 st) of material when blasted.

Loading

Loading of haulage units is accomplished with 12 electric shovels varying in dipper sizes from 11.5 to 15 m³ (9 to 22 yd³). All shovels are powered by 4160 V via trailing power cables. Two 9.2-m³ (12-yd³) front-end loaders are used for cleanup operations and low bank loading and also serve as backup units to the shovels.

At Morenci, loading consists of production loading of all material at the mining face. Nonore material is delivered by truck to the dump while ore is delivered to several transfer locations. Once the ore has been delivered to the transfer site, it is reloaded onto trains and is transported to the concentrators.

Reloading of the ore is accomplished using three methods which include conventional 11.5 m³ (15 yd³) shovels, hydraulically operated drop chutes, or a mechanized feeder hopper.

Approximately 40% of ore is transferred onto rail by the drop chute method, 27% by the pan feeder and 33% conventionally. The pan feeder is the newest method of transfer loading incorporated at Morenci and consists of a large bin structure with a reciprocating pan feeder attachment at the base. The locomotive engineer operates the feeder and spots the train simultaneously resulting in a quicker, safer and more uniform loading process.

Construction of an in-pit crush convey ore handling system is scheduled for completion in 1989 which will replace all ore transfer at Morenci.

Shovel operators work three-shift-rotation on a continuous schedule. There are four shovel crews, each of which works seven days with two or three days off between shift changes. This schedule allows a continuous staffing with each employee working only one overtime day per month. In addition, a relief system for production personnel is utilized whereby employees are relieved at their equipment rather than being transported to the mine office or change room for relief.

Haulage

Haulage of material out of the Morenci pit is accomplished with trains and trucks. Presently all ore grade material is transferred onto trains for delivery to the concentrators. Trains are 15 33-m³ (43-yd³) capacity side dump cars mobilized by either 1306- or 1492-kW (1750- or 2000-hp) diesel-electric locomotives. The caboose is a side dump car that has been outfitted with an enclosed riding platform containing a seat, heater, two-way radio, and air gauges to indicate the pressures in the air brake systems. To

Fig. 3. Aerial view of the Phelps Dodge Corp.'s Morenci mine with the Metcalf mine in the background.

provide a headlight for the caboose, an air-powered generator is used, operated by compressed air from the dump line on the train. Each train is operated by one employee via radio remote control. The remote-controlled locomotive system at Morenci is the largest of its kind in the world. The locomotive engineer carries a packset on his or her shoulders and a control head on the belt that enables the engineer to transmit signals to the throttle, all brake systems, wheel sanders, horn, and the headlights when he or she is located at either end of the train or on the ground in the near vicinity of the train.

Until the advent of remote control operation, two-man train crews, consisting of a locomotive engineer and a brakeman, were utilized. One-man operation of trains has significantly reduced the cost of train operation. Fail-safe features are built into the equipment, including automatic air application to stop the train whenever a coded tone radio command is not received clearly or whenever the locomotive engineer's body assumes a position more than 45° off vertical. Remote control enables the driver to have full control of the train from the leading end—whichever direction he is traveling.

Computer-controlled dispatching of rail and truck traffic has been installed in the Morenci pit, similar to the system for dispatching haulage trucks in operation at Phelps Dodge's Tyrone mine at Tyrone, NM. The system has increased effective operating time by reducing queuing at shovels and crushers. It incorporates on-board radio telemetry along with roadway sensors to measure and report train or truck location. With the addition of computerized dispatching, the productivity increases have offset the purchase cost of additional equipment to maintain production.

At the concentrators each train of ore is dumped pneumatically by the locomotive engineer. Each car is spotted at the dump pocket and a lever is pulled to open the valve that activates the dumping air cylinders.

Each train completes three to four cycles per 8-hr shift. The haulage operation, just as the loading operation, is continuous, operating 24 hours per day, seven days per week. A relief system for equipment operators identical to the loading operation relief plan is used.

The Morenci mine has a fleet of 28 haulage trucks rated at 154-t (170-st) pay-load capacity. Each of the trucks is powered by a 16-cylinder (1600- or 1800-hp) diesel engine that drives an a-c traction alternator that, in turn provides power to two d-c electric wheel motors that drive the rear dual wheels of the trucks. The trucks primarily are loaded by large electric shovels equipped with 16.8-m³ (22-yd³) dipper.

Historically, truck haulage in the Morenci mine accounted for less than 10% of the material moved. Recently, however, the accelerated development on the lower levels of the pit has increased truck haulage to 100% of total daily production while trains are utilized for ore transfer. Truck haulage will continue to be used in the Morenci pit in conjunction with other haulage methods. The in-pit crush and convey system that is scheduled to come on line by 1989 will replace rail haulage at Morenci.

9.5 Case Study: Cuajone, Peru

DANIEL RODRIGUEZ HOYLE

Respectfully dedicated to my friend Frank W. Archibald,
formerly Chairman and President, Southern Peru Copper Corporation

INTRODUCTION

In December 1969, an agreement (the Cuajone Bilateral Agreement) was reached between the Peruvian government and Southern Peru Copper Corp. (SPCC) on a specific program to develop and operate the Cuajone ore body. The Agreement provided a maximum time limit of 6½ years for the placing in operation of the Cuajone project, with all financing, construction, and operation being the responsibility of SPCC. The government undertook to grant SPCC the benefits, terms, and guarantees contained in the then existing Peruvian mining legislation.

Cuajone is the second large investment made by SPCC in Peruvian mining. The first was the development of the Toquepala deposit, located 24 km southeast from Cuajone. Toquepala started production in January 1960 and, with subsequent expansions, amounted to a total investment of US \$318 million by the end of 1982. Until 1976, when Cuajone started productive operations, Toquepala was the largest Peruvian copper producer. A summary of Peru's production covering the last three decades is given in Table 1.

Quellaveco, the third large ore deposit partially developed by SPCC, reverted to the state in 1971. At the time of its reversion, the reserves of this deposit were in the order of 191 Mt with an average content of 0.94% copper. In January 1972, the government assigned Quellaveco to its state company Empresa Minera del Perú (Minero Peru). The deposit is located 16 km north of the Toquepala mine and 11 km southeast of the Cuajone mine.

The Cuajone copper complex is owned 88.5% by SPCC and 11.5% by Billiton BV, a wholly owned subsidiary of the Royal Dutch/Shell Group. SPCC is owned 52.3% by Asarco Inc., 20.7% by the Marmon Group Inc., 16.3% by Phelps Dodge Overseas Capital Corp., and 10.7% by Newmont Mining Corp.

LOCATION

The Cuajone ore body is located in the Andes mountain range at 3500 to 3800 m elevation, 71 km from the Pacific Ocean in the Dept. of Moquegua in southern Peru. The deposit is sited 30 km northeast of the town of Moquegua. Fig. 1 shows the approximate location of the Cuajone and Toquepala mines, the Ilo copper smelter, the nearby Quellaveco ore body, and the nearest major cities.

DISCOVERY AND EXPLORATION

Copper mining in southwestern Peru was carried on sporadically since the end of the 19th century, and there are brief references in geographical literature of the time to copper occurrences in the general area of Toquepala and Cuajone. Narrow oxide and enriched sulfide veinlets were exploited on a very limited scale, but the desert nature and difficult accessibility of the area discouraged continued mining activities. Soon after the settlement of the border conflict between Peru and Chile in 1929, interest was renewed in the area and local residents started staking out mining claims. Prominent among these were Juan Oviedo Villegas (Toquepala) and Julio E. Gianella (Cuajone).

In 1937 the Toquepala and Cuajone prospects were recognized as potential porphyry-type copper deposits of major importance by geologist A. C. Schmedeman during an exploration mission for Cerro de Pasco Corp. Merit is due to Schmedeman for his geological insight, as the evidence of widespread copper mineralization in the two deposits was obscured by a deep leached capping mantle and/or thick post-ore volcanic rock cover.

Cerro de Pasco Corp. acquired mining rights to Cuajone in 1943 and explored the deposit during the period 1943 to 1945. The exploration program, which included the drilling of 40 diamond drill holes, was resumed by Cerro and New-

mont Mining between 1952 and 1954 when an additional 88 churn boreholes were drilled, guided in part by the findings of a self-potential and resistivity survey conducted in the areas covered by post-ore volcanics.

During the period 1965-1966, SPCC completed the exploration of Cuajone with an additional 83 diamond boreholes and established the grade-tonnage potential of the deposit for mining by surface methods. A number of shafts and adits were driven and approximately 9 kt of sulfide and oxide ore samples were treated at a pilot plant in Toquepala to investigate the milling characteristics of the ores and to define an adequate flowsheet.

Using a 37° final pit slope, a minable reserve of approximately 425 Mt of sulfide ore averaging 1% copper at a 0.45% cutoff and containing 0.025% molybdenite; 23 Mt of oxide copper ore at 1.29% Cu; 109 Mt of low-grade sulfide ore averaging 0.32% Cu; and 1052 Mt of waste material were dimensioned. The ratio waste:ore averages 2.8:1.0.

GEOLOGY

Areal Geology

The mineral district is characterized by a Jurassic(?)-Cretaceous-Tertiary basement of homoclinal volcanic flow rocks, tilted gently to the west that extend in a northwesterly trend along the western flank of the Andes and are contin-

uous units between Toquepala and Cuajone. Along the northeast they are unconformably overlain by Plio-Pleistocene volcanic flows, pyroclastic units, and tuff beds. Along the southwest they are covered by continental deposits of the Moquegua formation of Pliocene age.

The basement rocks have been faulted and intruded along a northwesterly belt by large masses of the Andean diorite batholith. Two diorite apophysis occur in the Cuajone area, one east and the other west of the mineralized zone.

An intrusive complex composed of quartz monzonite, quartz latite porphyry, and andesite stocks intrudes the basement volcanic rocks within the Cuajone mineralized area.

Basement Rocks

The basement volcanic rocks present in the mineralized zone are Cuajone basaltic andesite, Quellaveco quartz porphyry, and Toquepala dolerite. These rocks make up the southwestern, southern, and eastern sides of the ore body.

Intrusive Complex

The central, western, northern, and northeastern portions of the ore body are constituted by intrusive stocks. The largest intrusive is a quartz latite porphyry body 600 to 800 m wide that trends northwest and extends 4 km to the northwest of the deposit. The southernmost portion of the latite body is

located within the ore zone and the northern extension is unaltered and unmineralized.

The latite body has intruded an older monzonite rock, and roof pendant remnants of strongly altered, mineralized monzonite are found in the central and southern part of the mineralized zone.

The youngest intrusive rock is a fine-grained andesite that is thoroughly altered to quartz-sericite-chlorite and, in two separate bodies, cuts through the older intrusive rocks and basement volcanics along brecciated contacts. The bodies are nearly parallel, trend northeast, and are located in the northeastern and southwestern sides of the mineralized zone. A few narrow postmineral latite porphyry dikes cut basement rocks in the district.

Postmineral Volcanics

Two distinct groups of postmineral volcanics overlie the mineralized zone. The oldest volcanics, trachyte flows and tuffs, are found along the south rim of the mineralized area. A younger set of volcanic ignimbrite rock covers the northern half of the ore body.

Structures

The only major fault structure associated with the deposit cuts across the southwestern area of the ore body. Strike is N50°W with a steep dip to the southwest. The fault system or shear zone, 10 to 130 m wide, is filled with parallel tabular bodies of unmineralized postore angular breccia and barren latite dikes. Displacement of the basement rock sequences on both sides of the breccia body indicates a major premineral fault structure.

Widespread quartz veining lacework and intense rock jointing indicate a very strong preore-stockwork shattering action affecting the intrusive complex and surrounding rocks. Numerous small and steep fault systems with a predominant northwestern trend are common throughout the ore body.

Ore Body

The Cuajone ore body is composed of an upper, discontinuous, and roughly flat-lying layer of copper oxide mineralization that overlies a tabular layer of enriched sulfide. Directly beneath is the bulk of the ore body, composed of primary sulfides.

A capping of leached rock and postmineral volcanics covered the ore body almost entirely. This capping is a few meters thick along Quebrada Chuntacala in the central part of the ore body and up to 150 m thick on the southern and northern parts.

In plan view at its maximum areal extent, the ore body is oval in shape with the long axis oriented in a northwestern direction and measuring 1200 × 900 m approximately. The maximum horizontal extent of the ore body is found at the top of the enriched sulfide zone.

The ore body is funnel-shaped in depth; however, most of the lateral limits of ore are inclined inward at steep angles.

Copper Oxide Zone

The copper oxide zone is tabular and approximately horizontal, dipping gently to the west. Average thickness is 15 m. A total of 23 Mt of oxide material at 1.29% total copper exists within mining limits.

The predominant oxide copper minerals are malachite and chrysocolla. There are moderate amounts of tenorite (variety melaconite) and minor or trace amounts of brochantite, azurite, cuprite, and native copper. Some copper is also present in a brown to black amorphous form, probably a mixture of copper oxides and limonites. The oxide mineral

assemblage is intermixed with substantial amounts of chalcocite, minor covellite and pyrite, and trace chalcopyrite.

Enriched Sulfide Zone

The enriched or supergene sulfide zone underlies oxide copper mineralization or leached capping and overlies primary or hypogene sulfide mineralization. In areal extent it is only slightly smaller than the maximum extent of the primary zone.

The zone has a semi-horizontal tabular configuration and is inclined to the west. Maximum thickness is 78 m but the average is close to 20 m. There are approximately 57 Mt of enriched sulfide ore at 1.57% copper grade.

The aphanitic basic rocks, intrusive andesite, and Cuajone basaltic andesite have yielded the finely textured alteration minerals, chlorite and biotite, that were replaced by large amounts of fine-grained sulfides. The intermediate acidic intrusives have coarser textures and less replaceable alteration minerals. Therefore somewhat better copper grade is found where intrusive andesite and basic volcanics predominate.

Pyrite content is low over most of the ore body. The propylitic alteration halo contains large amounts of vein pyrite. Pyrite to chalcopyrite ratios prevailing over the main central ore-body zone are between 1:1 and 2:1. Total sulfide content of the primary zone ranges from 4 to 9% by weight.

Molybdenite occurs as small platy clusters and, to a minor degree, as fine disseminations. The average molybdenite content of the ore is 0.025%. Areas in the intrusive andesite bodies contain up to 0.04% molybdenite. Silver and gold occur in very minor trace quantities throughout the ore body.

In addition to the widespread hydrothermal alteration minerals—quartz, sericite, biotite, chlorite, and clays—prograde quartz veining pervades the ore-body host rocks.

Chalcocite is the predominant supergene mineral replacing chalcopyrite, bornite, and pyrite. Minor covellite and digenite are found as intergrowths with chalcocite.

Primary Sulfide Zone

The Cuajone ore body is essentially a hypogene copper deposit. Over 86% of the sulfide ore reserves tonnage estimated for the deposit is in the primary zone.

Mineral assemblage consists of major pyrite and chalcopyrite and minor bornite and molybdenite. Trace enargite, sphalerite, and galena occur in vugs within quartz veins and breccia dikes. The most abundant sulfide is pyrite and the principal copper sulfide is chalcopyrite.

Chalcopyrite dissemination takes two principal forms: as discrete and moderate to very fine grains dispersed among the quartz-sericite-biotite alteration minerals, and as irregular clusters replacing laths and aggregates. Veinlet chalcopyrite is not common.

Pyrite is found largely in narrow to thick veinlets along with quartz. A moderate amount is dispersed as grains or clusters.

Hydrothermal Alteration

The halo of hydrothermal alteration surrounding the Cuajone ore body is from 3 to 4 km in diam. From the center of the ore body outward, four main zones or stages with diagnostic alteration mineral assemblages have been established: a central zone, entirely within the ore body that contains strong quartz-sericite, moderate clay, and minor potash feldspar; an outer zone within the ore body in Cuajone basaltic andesite that shows moderate to strong clay and biotite alteration; a zone of propylitic alteration at the limit of the ore body and beyond; and a zone at the limit of the ore body and beyond, only within Quellaveco quartz porphyry, that

has pervasive silicification. The quartz latite dike carries interstitial carbonate. No significant tourmaline or anhydrite has been found.

FEASIBILITY STUDIES

Coincidental with the final Cuajone exploration phase (1965-1966), SPCC started feasibility studies through metallurgical testing of drill cores. Enriched and primary ores, as well as the various host rock types, were treated in this manner. During 1965, a 36 t/d pilot plant was erected at Toquepala to test bulk samples of Cuajone ores. Aside from conventional grinding and flotation, the material was also tested for autogenous grinding, but the results were not sufficiently conclusive to incorporate autogenous mills in the final plant design. The ore posed no serious metallurgical problems, except for some high clay ore types with slime-producing characteristics.

Column and heap leaching of Cuajone oxide ores, followed by solvent extraction and electrowinning, were also extensively tested at the pilot plant with very satisfactory results.

At the same time, a stripping and mining plan was developed, which included 136 Mt of premine stripping for an initial 27 kt/d ore production rate. The pit was to be mined using 15-m high benches, 7.6-m³ electric shovels, and truck and train haulage.

In 1973, the mining plan was modified to support a production rate of 40.8 kt/d of ore. That resulted in an increase to 236 Mt of premine stripping and the redimensioning of all equipment capacity.

In 1970, Fluor Utah Inc. was awarded the project's general contract for engineering and construction as well as management of subcontract work with local firms. However, SPCC maintained control in specific development areas such as basic mill and railroad design, mine and strip planning, ground-water exploration and development, exploration for aggregates, and all foundation engineering geological investigations. Engineering design was performed at San Mateo, CA, and at Lima and Toquepala in Peru.

The most critical factors in the overall Cuajone project design were the concentrator site location, the choice of concentrate conveyance routes, the disposal of mill tailings, and the procurement of an industrial and domestic water supply.

The Cuajone concentrator site finally selected is located at Botiflaca, 8 km southeast of the mine, the closest area to offer topographic construction advantages and expansion possibilities and at the desired elevation for the primary crusher to correspond with the designed pit exit level.

Rail transport offered the advantage of concentrate haulage from Cuajone to the existing Toquepala-Ilo-Industrial railway and of economical transportation of supplies from the port area and was considered a logical extension of the accessways serving Toquepala. But the rough terrain separating Cuajone from Toquepala, consisting of parallel drainageways that have dissected a high volcanic plateau and carved numerous deep NE-SW canyons in the region, ruled out the convenience of building a surface railroad. Tunnel alternatives were, therefore, investigated in great detail. Thirty-one alignments were analyzed and their geologic conditions studied in order to arrive at the final route consisting of 30 km of railroad, including five tunnels with an aggregate length of 27 km.

Because of the rugged topography, steep-gradient canyons, occasional flash flood conditions, and seismic risk, it was decided from the start to dispose of mill tailings into

the sea through, essentially, the same outlet taken by the Toquepala mill tailings.

Water resources in southwestern Peru are very scarce and the few agricultural valleys and settlements have first priority on its usage. A short—two- to three-month—yearly precipitation regime and the lack of natural storage possibilities result in cyclical water shortages. Water supply for the project, estimated at a maximum rate of 1500 L/s, either had to be imported from distant Andean water sheds, or to be developed from highland ground-water sources. US consultants in the fields of hydrogeology and geophysics and company geologists were successful in proving and developing an extensive aquifer—the Capillune Formation—50 km northeast of Cuajone, at 4450- to 4550-m elevation, that satisfied the project's requirements.

Considerable studies for the expansion of SPCC's Ilo copper smelter and power plant on the sea coast were made, in order to handle the new Cuajone concentrate production and to satisfy the energy demands of the project.

Two new modern townsites were designed to be built to house the staff and workers and their families, necessary for the operation of the Cuajone mine and concentrator. Likewise, the expansion of the Ilo Camp was planned.

The construction of offices and other service buildings and the equipping of service shops and similar permanent and temporary installations were programmed in detail.

Paramount in the design of the Cuajone complex components was the need to integrate them smoothly, efficiently, and economically into the Toquepala infrastructure.

CUAJONE BILATERAL AGREEMENT

The Cuajone Bilateral Agreement is a case study in international mining transactions: it represented an important investment; was negotiated and carried out within circumstances of high political and economic risk; and was innovative in its financial and legal conception.

Antecedents

By Public Deeds of November 1954 and April 1955, the government of Peru and SPCC signed contracts for the exploitation, as independent units, of the Toquepala, Cuajone, and Quellaveco mineral deposits.

The company initiated its operations with the exploitation of Toquepala in 1960. This was effected under a bilateral contract which, in compliance with Law 16732, ended on Jan. 1, 1968. Said Law stated that new conditions would be negotiated for the exploitation of both the Cuajone and the Quellaveco mines.

The second clause of the Cuajone Bilateral Agreement, signed on Dec. 19, 1969, states that the Quellaveco ore body is the subject matter of a separate contract. However, as stated before, Quellaveco reverted to the state in January 1971.

Cuajone Agreement—Company's Obligations

Under the terms of the agreement, the company undertook the obligation to build the necessary installations, invest and obtain the corresponding financing, and operate the mining complex at a minimum ore production rate of 27.2 kt/d (all of the equipment and installations, including water and power supply systems, the smelter expansion, etc., to match this goal). The necessary investment was estimated to be US \$355 million and the maximum construction period was fixed at 6½ years.

Modification in the Scope of the Project

In fact, as will be seen later in this section, it became necessary during the project's construction to substantially enlarge the size of the principal and many auxiliary installations. This increase in productive capacity was in the order of 50% in excess of what the bilateral agreement specified, and was the result of the decision made by the company to maintain a reasonable investment-per-ton-of-installed-capacity ratio. The initial estimated ratio was approximately US \$3000 per 0.9 t/a of blister copper [US \$355 million per 108.8 Mt/a of copper]. The decision to increase the scope of the project was triggered by the worldwide inflationary trend brought about by the abrupt change in the price of oil by OPEC in 1973. The resulting unit investment was US \$4150 per 0.9 t/a. This relatively low ratio was met because the company had already carried out much of the infrastructural work and had firm purchase orders for an important proportion of the equipment and raw materials required during the construction phase of the project.

This case study does not describe the installations that the company undertook to carry out in compliance with its obligations under the bilateral agreement. Due to SPCC's decision to increase the scope of the project, the description and size of the various project components are shown here as they were actually built and the corresponding investments also as those effectively made.

Should SPCC have failed to comply with its contractual obligations, the penalty would have been the voidance of the concessions in the following cases:

- That SPCC should not invest or undertake duly verified expenditure commitments of a minimum of US \$25 million, during the first 18 months of a work schedule to begin on Apr. 1, 1970.
- That within an 18-month period, counted from the date of signature of the agreement, SPCC should not assure the financing necessary for the continuation of the investment plan, submitting the corresponding scheme and/or assuming responsibility for executing said plan by its own means, accrediting said facts, as the case may be, with the pertinent documents. If, during any year, the company would not have invested at least 60% of the amounts corresponding to the annual investment programs, these conditions would have been considered as not having been met.
- The nonconclusion of the construction work within the period of 6½ years would terminate the project and obtain the minimum production.

The time corresponding to these penalties would not be counted in case of fortuitous or *force majeure* cases, such as strikes, wars, or any other that may have impeded the start or continuation of the works, despite the desire of the company to carry them out on schedule.

The company agreed not to transfer, adjudicate, convey, or, by any other means, deliver the agreement to third parties without the prior consent of the government.

The agreement specifies that it may be modified only by means of public deed, once the contracting parties have agreed upon such modification.

Finally, the company declared its express subjection to the laws and law courts of Peru, and forewent recourse to diplomatic protection regarding this Agreement.

Government's Obligations

In consideration for the investments to be made by the company and the execution of the works subject matter of the project, the government agreed to grant to the company the concessions, authorizations, permits, easements, rights,

water rights, rights of passage, right-of-way, and other facilities that may have been requested by the company. The government further agreed to grant the support that may have been pertinent and legally possible for the negotiation and successful conclusion of the loan agreements that the company may have requested from foreign government institutions or from international financial institutions, without the government assuming any economic obligation whatsoever, nor affecting the interests of the state.

This did not imply, either directly or indirectly, that the government would have assumed or assumed the obligation to grant any security or collateral as a guarantee for the obligations that the company may have incurred.

The company agreed to deliver to the Central Reserve Bank of Peru, directly or by means of deposit in the name of the Central Reserve Bank in a corresponding bank abroad, the total amount of the foreign currency that it would receive as the f.o.b sales price of its export products. In exchange, the Central Reserve Bank of Peru undertook to furnish to the company immediately, for a value equivalent to the amount delivered to it, foreign exchange certificates issued nominatively and transferable by endorsement that may be necessary to meet payment of SPCC's invested funds; the interest on loans that may have accrued provided it had been taken into account in fixing the amount of the investment; and such justified services that the company would meet in the country or abroad to remunerate technicians engaged by the company, up to a certain specified limit.

In fulfillment of the guarantee for disposability granted under the preceeding paragraph, and for the purposes described therein, the Central Reserve Bank of Peru agreed to deliver to the company the necessary foreign exchange, against submittal of the corresponding certificates in the amounts necessary to cover the "Investment Recovery Program" (see further on in this section).

It was agreed by the Central Reserve Bank of Peru to grant to SPCC the guarantee of disposability of foreign exchange during the period of recovery of the capital invested.

The company agreed to register with the Central Reserve Bank of Peru—during the construction period—the documents certifying its imports and, in general, all receipts considered in the investment plan and in the investment recovery program.

The delivery of foreign exchange to the Central Reserve Bank of Peru would not be applicable in the cases of capital from loans obtained abroad that were earmarked, also abroad, for the purchase and importation of equipment, materials or other capital goods, or for other expenses and services included in the investment plan, but these investments had to be registered with the Central Reserve Bank of Peru.

The government granted free disposability for the export and sale by the company of the products and byproducts of the Cuajone mine. Therefore, no measures could be applied that would:

- Restrict the right to sell to any destination, once the needs of the local national consumption were met in the manner established by law.
- Suspend or postpone the said sales and/or exports.
- Require the sale in any foreign market at prices lower than may have been obtained in the international markets where the major part of the company's exports would be placed.
- Require the payment for the said products on the basis of barter or in currencies not valid for international payments.

The company was authorized to invest, after expiration of the agreement, for a period not to exceed five years, up to 50% of the net profit of each fiscal period in the establishment of refining plants and/or plants for the conversion of metallurgical products.

The government agreed to grant to the company authorizations and facilities for temporary imports, as well as for the sale or reexportation of such equipment or materials imported and specifically used during the construction period of the project. It also granted partial exemption from payment of certain customs duties on the imports of specialized equipment.

On the other hand, the company was required to acquire materials of national production, provided they should be available, in sufficient quantities at the time they would be required; of quality that would conform to the specific needs of the mining industry; be functionally adequate, and have competitive prices, the latter limit to be considered when the value of the national product did not exceed by more than 25% the CIF value of the similar foreign product.

Investment, Recoverable Investment, Investment Recovery Period

It was agreed that the taxation system, including the tax stability regime, would be applicable during the period required for the recovery of the investment, a period not to exceed 10 years, counted as from the date of start of mining exploitation operations at Cuajone (the 10-year period could be extended up to a maximum of 20 years under exceptional conditions, such as unforeseen very extended price depression periods).

For the purpose of determining the actual period for recovery, "Investment" was defined as the *cumulative* disbursement made in the purchase of equipment and machinery, the expenses of preparation and installation, the expenses of construction, and the interest on the loans, that is to say, all expenses incurred during the period comprised between the dates of initiation and completion of the project, up to the start of mining exploitation operations, including working capital and the losses due to exchange differences arising from credits, insurance, expenses, commissions, or premiums obtained abroad.

This all-encompassing investment figure would, however, be reduced, for contractual purposes, by the amount that the company could reinvest in the project from depletion reserves originating in other mining operations in the country (such as Toquepala). The resulting *cumulative* figure would be defined, under the agreement, as "recoverable investment."

The concept of recoverable investment had no other effect but to *help measure the time period* during which the taxation system, including the tax stability period, would be contractually applicable.

Once having started mining exploitation operations, the company would retain from its Cuajone profit and loss statements, prepared under Peruvian tax legislation, the following items of cash flow:

- The total profits, less the taxes thereon applied.
- The depreciation of the fixed assets, less all government-authorized investments made by the company subsequent to the initiation of operations.
- The depletion reserves originating from the Cuajone unit operations.
- The amortization of the mine preparation expenses.
- The interest accrued on the investment of capital obtained by loan, provided it had been considered in fixing the amount of the investment.

- The total of any ordinary or extraordinary reserves the company may make, with the exception of those reserves or provisions intended to cover the social benefits of employees.

The sums thus retained would constitute the "recovered investment" for the period in question. These recovered investments would be added from year to year and constitute the *cumulative* recovered investment.

The investment recovery period would be determined by the time elapsed to accumulate recovered investments into such a sum as to equal the recoverable investment.

At this point in time, the taxation system applicable to Cuajone would change rates (see further in this section) and remain at the new rate for a period (tax stability period) of exactly six years, after which the Cuajone operations would be subject to any tax rates then generally applicable in Peru.

The foregoing Cuajone agreement tax formula, which followed Peruvian legislation to the letter, provides a sophisticated solution to the complex problem of determining the contractual time period during which a given tax structure would apply. The formula allows for the precise determination of a *variable* contract period. Should, for instance, the operating company enjoy exceptionally high prices for its products, the period during which it would pay preferential tax rates would be correspondingly shortened, and vice versa. Consequently, neither the host country nor the investor company would suffer unduly for having agreed to certain terms for a *fixed period of time* during which *luck*, good or bad, for any party in the contract, would result in detriment or in windfall benefit to the other party.

Taxation System

The parties agreed on the following taxation system:

- Apply to the taxable income resulting from the operation of Cuajone, during the *investment recovery period*, a total of 47.5%. This tax rate would be raised to 54.5% during the *tax stability period*, comprising the six years immediately following the investment recovery period. This taxation system contractually exempted the company during the two aforementioned periods, from all other tax created or to be created, whether national, regional, or local, as well as from any other taxation upon the concession or upon the products obtained therefrom. The exemption covers the company from liens or obligations that might represent a reduction of its cash resources, such as forced investments, forced loans, and tax advances, except the 4% of the value of exports on account of the income tax paid by all mining concessionaires in Peru. The company has the right to deduct from any year's net income the losses it may have suffered during the preceding five years.

- Depreciate the fixed assets on a global weighted rate between 3% and 12%, to be determined annually by the company, with the objective of eliminating, by means of this system, the payment of taxes abroad.

- Calculate the depletion reserves originating from the Cuajone unit operations in accordance with the applicable mining and tax laws existing on the date of signature of the agreement. These were limited to the smaller of two values for any one year: 15% of the gross value of the mineral production or 50% of the profits, after having deducted the depletion allowance itself.

- Amortize the mine preparation expenses, which include the cost of prospecting, preparation, and development of the mine and removal of the overburden during the pre-operative stage, at a rate of 10% per year.

- Amortize the interest accrued by the investment of capital obtained from loans, provided it had been considered

in fixing the amount of the investment, at an annual rate of 5%.

- Retain any ordinary or extraordinary reserves the company would make, with the exception of those intended to cover the social benefits of employees, which must be kept inviolate.

For the purpose of determining the investment and its recovery, the company was authorized to carry an auxiliary book with a special account in US currency.

The company was also authorized to revalue annually, tax-free, the fixed assets and the mine preparation expenses, and to apply amortization and depreciation on the readjusted value of said assets, with the exception of repair parts and accessories, when there may occur fluctuations in the value of the national currency in relation to the US currency in excess of 5% per year.

It was agreed that the accounting systems of Toquepala and Cuajone would be carried out independently, with detailed provision being made in the agreement for attaining this objective.

CUAJONE INVESTMENT, FINANCING, AND RECOVERABLE INVESTMENT

The investment made in Cuajone and the financing of the required funds are summarized as follows:

Total Investment

The total investment made in Cuajone was US \$746.9 million. The application of funds by work centers is given in Table 2. Table 3 shows the application of funds in chronological order.

Financing

Source of Funds: Cuajone was financed through equity participation, direct cash credits, equipment suppliers' credits, and copper purchasers' credits, as shown in the following table:

	Million US\$
SPCC equity, Including Reinvestment of Depletion Reserves Originating from Toquepala	310.4
Billiton BV-Capital Association Participation	24.8

Direct Credits	215.7
Equipment Suppliers' Credits	142.0
Copper Purchasers' Credits	54.0
Total Investments: Source of Funds	746.9

Recoverable Investment

For the purpose of application of the Cuajone Bilateral Agreement (see pertinent section), the project's recoverable investment was determined as follows:

	Million US\$
Total Investment	746.9
Toquepala Depletion invested in Cuajone	(74.6)
Working Capital difference	(19.6)
Mining Community—Workers Participation System	(22.5)
Cuajone Recoverable Investment	630.2

Recovered Investment

Table 4 shows the contractual recovered investment figures for the period 1977-1981.

PRODUCT SALES DISTRIBUTION

The Cuajone copper production is allocated in accordance with sales contracts subscribed on Sep. 19, 1974, as follows:

Cuajone Copper Sales Contracts

Contracts for First 90.7 kt/a of Blister: Duration of the contracts is 15 years after production start-up.

CUAJONE MINE—OPERATIONS

Premine Stripping

To prepare the pit for an initial uniform production of 27 kt/d of ore, it was originally planned to remove about 136 Mt of waste material during the construction phase of the project. Actually, when the premine period was concluded and mine production started on Oct. 21, 1976, at an ore rate of 40.8 kt/d, SPCC had removed 239 Mt of waste, including approximately 90 Mt of material that was used in the construction of a dam across Quebrada Chuntacala to connect the north and south portions of the pit and also prevent possible flooding by sporadic local rainstorms.

Mining Operations

Cuajone, like Toquepala, is mined by open pit methods. Both operate on a six-day-per-week schedule.

Most of the waste material is directly transported by trucks to the dump areas, while the minor tonnage is hauled by rail-truck combination through loading docks. Approximately 50% of the ore is hauled by trucks to the pit's loading dock for transfer to the trains; the other 50% is loaded directly on trains, also for delivery to the primary crusher. The oxide and low-grade sulfide ores are transported by trucks to selected dumps.

Normally, the 11.5-m³ shovels are worked in waste while the 6- and 6.9 m³ shovels are operated in ore. The 109-t trucks generally haul stripping waste only, while the 90- and 45-t trucks are employed either in ore or in nonore material (waste, oxides, and low-grade sulfides). The haul roads average 25 m wide and have maximum grades of 8%. Each train consists of 12 38-m³ cars drawn by a 1.7 MW GE locomotive.

ANFO is the normal blasting agent used, but Slurrex is employed for wet holes. The drilling pattern varies widely but averages 8 × 6 m. Tricone bits of 311 and 270 mm are currently used in primary drilling, and 76- and 63.5-mm bits are normally used in secondary blasting.

Major Mining Equipment

Initially, Cuajone had available the following major mining equipment capable of removing about 63.5 Mt/a of rock. Equipment consisted of 10 1.7-MW Diesel locomotives and 115 railroad cars; 7 11.5-m³ PH-2100 shovels; 3 6.9-m³ PH-1800 shovels; 2 6-m³ M-152 Marion shovels; 9 Bucyrus Erie rotary drills; 22 90-t M-100 Lectra Haul trucks; 20 109-t Wabco trucks; 8 Haulpack 45-t trucks; and front-end loaders, dozers, medium and light trucks, heavy graders, compressors, drills, cranes, and mobile equipment.

Mine Operating Summary

An operating summary of the mine is given in Table 5. The general mining operating summary to Dec. 31, 1981, is given in Table 6.

CUAJONE CONCENTRATOR OPERATIONS

Location and Capacity

The site at Botiflaca, about 7 km west of the Cuajone mine at an average elevation of 3400 m above sea level, was selected and the concentrator, with a capacity to treat 40.8 kt/d, was built. The design allows for an economical expansion of processing capacity to 49.9 kt/d.

Topographic conditions required the excavation and removal of over 9 Mt of rock at the concentrator site. In addition, over 3.6 Mt of material were excavated and removed in foundation work done for the concentrator and in constructing ancillary installations.

The Cuajone mine and Ilo industrial railroads interconnect in the concentrator area.

Description of the Process

The ore is transported from the mine to the 1524-mm primary crusher by a 9-km long railroad system in 91-t side

dump cars. Undersize and 190.5-mm crushed ore are conveyed to the intermediate ore storage from which it is fed to two 2-m standard and six 2-m short head secondary and tertiary crushers, in closed circuit with ten 1.8 \times 4.9-m vibratory screens. The —12.7-mm product is transported to the fine ore storage from which the eight grinding sections will be fed. All material movements are effected by belt conveyor systems.

Each grinding section consists of a 5 \times 6-m ball mill, driven by a 2238-MW motor, operating in closed circuit with eight 508-mm cyclone classifiers with corresponding pumps.

The cyclone overflow pulp from all sections passes a sand-slime separation circuit—a very important result of the massive pilot plant tests—consisting of 48 254-mm cyclones with pumps. Sand rougher flotation is effected by 132 2.3-m³ cells; the slime is treated by 84 8.5-m³ rougher cells. The tailings are discharged into three 131-m diam center caisson-type thickeners from which water is reclaimed and pumped back to the mill circuits.

After regrinding in four 3.2 \times 5.2-m ball mills, the concentrates are cleaned, recleaned, and scavenged in 124 2.8-m³ flotation cells. The scavenger tailings are conveyed to the tailings thickener; the concentrate joins the feed to two 61-m diam middling thickeners for recycling in the regrind circuit.

The recleaner concentrate is treated in the molybdenite recovery section or sent directly to a 48.8-m diam thickener and fed into four 3.6 \times 5.5-m drum filters and later into two 3 \times 18.3-m stainless steel rotary dryers.

Water recovered from the concentrate and middling thickeners joins reclaimed water from the tailings thickeners.

Products

The copper concentrate is transported to the Ilo smelter by railroad cars through the five-tunnel system. The moly concentrate is also transported by railroad to the Ilo port for shipment.

The Cuajone tailings flow by gravity through a pipeline system, installed in railroad tunnels Nos. 1 to 4, to join the Toquepala tailings at Quebrada Simarrona and from there flow to the ocean.

Molybdenite Recovery Section

The molybdenite recovery section of the Cuajone concentrator has an installed capacity of 2.3 kt/d of copper-molybdenum concentrate.

This section incorporates feed aging tanks, attrition-conditioning equipment, rougher flotation cells, two stages of regrinding, and eight cleaning flotation stages.

ASMOL copper depressants are applied in the rougher and first cleaner steps and sodium cyanide in subsequent cleaning steps. The thickened final moly concentrate is leached with cyanide, filtered and washed in two stages, and dried and packaged in metal drums. The molybdenite recovery section started production in June 1980.

Flux and Low-Grade Stockpile

Higher grade Cuajone mixed oxide-sulfide ores are crushed, screened, and transported to the Ilo smelter, at the rate of about 900 t/d for use as siliceous flux.

Other oxide ore and low grade sulfide [combined reserves in the order of 132 Mt] are being stockpiled at Cuajone for leaching at a future date.

Table 6. General Mine Operating Summary Up to Dec. 31, 1981

Major Concentrator Equipment

A list of major Cuajone concentrator equipment is given in Table 7.

Concentrator Operating Summary

An operating summary of the concentrator is given in Table 8.

Cuajone Molybdenite Recovery

A summary of the Cuajone molybdenite recovery section is given in Table 9.

General Concentrator Operations

The general concentrator operating summary up to Dec. 31, 1981, is given in Table 10.

ILO SMELTER EXPANSION, OPERATIONS

Location and Capacity

The SPCC Ilo smelter, located on the seacoast, 17 km north of Ilo port, has processed the Toquepala mine copper concentrates since 1960. The production capacity of this smelter [127 kt/a of blister copper] was expanded—within the Cuajone project—to a total of 290 kt/a of blister to process the combined productions of both mines. This capacity allows for the normal fluctuations in concentrate grade and tonnage of the ore treated in the two concentrators.

New Major Installations

A modern materials handling system was constructed to replace the old clamshell bucket installations. The concentrate and flux ore materials are now discharged by a rotary car dumper and transported by conveyor to feed the reverberatory furnaces.

Two new 11-m wide by 35-m long side-charging reverberatory furnaces have been installed to treat 1 kt/d of concentrates, flux, and flue dust. The gases generated by these furnaces are processed through four waste-heat boilers and a new Cottrell precipitator system before they are discharged through a new 5-m diam by 107-m high acid-brick-lined concrete stack.

On the converter side, three new 4-m diam by 11-m long furnaces have been installed. In addition, the capacity of one of the four original converters was enlarged. Waste gases are emitted through a new 5-m diam by 107-m high acid-brick-lined concrete stack after being processed by a new Cottrell precipitator system.

The product from the converters is transferred to two new 4-m diam by 11-m long holding furnaces or to the two original holding furnaces. Blister copper is cast in a new 9-m diam 26-mold casting wheel and in the original 24-mold casting wheel.

Finished blister copper is transported by rail to the Peruvian government Ilo refinery or to the Ilo port to be shipped abroad through SPCC's Ilo industrial pier.

The increased consumption of heavy fuel oil by the smelter and the power plant has required erection of additional fuel oil storage tanks.

A second Calciner (hearth-type) kiln capable of producing an additional 113 t/d of lime from coquina shells has been built to satisfy the increased demand. The coquina heavy-media separation plant, located 10 km south of Ilo, was improved and expanded accordingly.

The repair shop and warehouse capacities were enlarged. This required the construction of new buildings and the expansion or relocation of existing ones.

Slag, matte, flux, and other material handling systems were enlarged to satisfy the new plant requirements.

Ilo Smelter Major Equipment

A list of Ilo smelter major equipment is given in Table 11.

Smelter Operations

An operating summary of the Ilo smelter in 1981 is given in Table 12. A general smelter operating summary up to Dec. 31, 1981, is given in Table 13.

POWER GENERATION, TRANSMISSION, AND COMMUNICATIONS

Power Generation

To satisfy the Cuajone electrical requirements, the existing 110-MW nominal (77-MW net) SPCC Ilo power plant was expanded with the installation of a new 66-MW steam turbine generator. The steam requirements of all generating units are supplied by the four waste-heat boilers connected to the two original reverberatory furnaces in the smelter, by the three already installed direct-fired boilers, and by the four 43 092-kg/h waste-heat boilers that were installed in connection with the two new reverberatory furnaces required for the Ilo smelter expansion.

To provide adequate cooling water for the new turbine, the original seawater intake system was improved and expanded. This required the construction of new pumping, desanding, and piping installations.

The Cuajone water supply system included the installation of two 4.5-MW hydroelectric generating plants. Although the principal object of these plants is to provide power for operating the pumps in the water supply system, they are fully integrated into the company's electrical generation and transmission network.

All of these installations are connected to the government's Aricota hydroelectric system and operate under power-interchange contracts by which the company supplies energy to the cities of Ilo and Moquegua and is, in turn, supplied with the same amount of power from Aricota.

Power Transmission

The power generated at Ilo is transmitted to Toquepala and Cuajone through a Ilo-Toquepala-Cuajone-Ilo power loop, using the original Ilo-Toquepala line and the new 138-kV Toquepala-Cuajone (32-km) and Cuajone-Ilo (84.9-km) lines. For this purpose, it was necessary to expand the Ilo and Toquepala substations and to build the Cuajone substation. An additional substation was installed in Tala in the Toquepala-Cuajone line to supply energy, on a temporary basis, for the Cuajone tunnel system construction.

In addition to the main transmission system described, it became necessary to install transmission lines from the Cuajone substation to other substations in the mine (69 kV, 6.5 km) and the Cuajone hospital and townsite areas (13.8 kV, 6.5 km).

A 52-km long 69-kV transmission line from Cuajone substation to the pumping station at Lake Suche was installed to serve the water supply system needs. This line connects to the two 4.5-MW hydroelectric generating plants.

To supply power to the construction sites, shops, and provisional camps, 24 km of temporary transmission lines and eight substations were installed during the construction phase of the project.

Communications

The communications requirements between the different areas of Cuajone and between these areas and the installations in Toquepala and Ilo were satisfied by the installation of an

automatic telephone system with exchanges at the mine, the main office, the concentrator, the hospital, and the townsites and by a radio system that supplies communication with Lima. A telephone system, connected to the government's national telephone network, has been incorporated.

A portable-unit radio communication system has been installed in the vehicles of the operation, maintenance, and supervisory personnel. This system is controlled from a fixed central station and was extensively used during the construction phase.

WATER SUPPLY SYSTEM

Studies

A water evaluation study started in 1967 in the Vizcachas River-Pasto Grande watershed, which had been reserved by

the government for the Cuajone project as per terms of the Bilateral Agreement, proved a firm supply of only 1000 L/s, not enough to fully satisfy the needs of the project.

Consequently, investigations centering on the development of underground water sources were initiated by SPCC. These studies were successful in discovering a large aquifer with sufficient capacity to satisfy the project requirements.

New Sources

A water supply system was installed and operates for industrial and domestic purposes of the concentrator and mine. Two small hydroelectric power generating plants, metallurgical and leaching systems, townsites, tailings disposal, etc., were designed and built to the necessary supply capacity to serve the installations that compose the Cuajone unit.

SPCC has developed up to 1500 L/s that can be pumped

Cuajone final needs	1500
	2500

Supply System

The Cuajone project main water supply system consists of a floating pumping station on Lake Suche and a high pressure booster pumping station located on its shore. This installation lifts the water approximately 220 m over a distance of 7 km through a 965-mm diam steel pipeline. From this point, the water flows by gravity through a 864-mm diam, 44-km long resin-reinforced fiberglass pipeline to the Cuajone concentrator area. This pipeline also conveys water

collected through a feed line from the Titijones basin wells field.

In the future, when the Cuajone and Toquepala units are expanded and their operations need more water, additional flow will be pumped from wells located in the Huaitire-Gentilar and Vizcachas Lake basins.

A 700,000—m³ reservoir was built at Viña Blanca, a site located between the two 4.5-MW hydroelectric generating plants near Cuajone. This volume can satisfy the fresh water requirements of the mine-concentrator complex during emergencies.

New Ilo Seawater Desalination Plant

The expansion of the Ilo smelter and other installations at Ilo, required an additional volume of water. To satisfy this need, SPCC built a 42-L/s seawater desalination plant, similar to the one already serving the then current Ilo smelter-Toquepala operations, which has a capacity of 32 L/s.

TUNNEL SYSTEM, INDUSTRIAL RAILROAD, AND TAILINGS DISPOSAL

Introduction

The original 206-km Ilo-Toquepala industrial railroad was extended to the Cuajone area, through a 30-km line of which 27 km were through tunnels. These tunnels allow for the installation of a standard gage railroad track and a pipeline system to convey the tailings by gravity from the Cuajone concentrator to Quebrada Simarrona, to mix with the Toquepala concentrator tailings, and from there flow down 93 km of dry creeks until reaching the Pacific Ocean at Ite Bay.

Preliminary Studies

Geologic studies of the areas to be crossed by the tunnels, including the drilling of approximately 4800 m of exploratory holes, were made during several years. Based on this geological exploration, tunnel support studies were made and the conclusion reached that probably 51% of the total tunnel length would not require support, 29% would require bolt and wire mesh support, and 20% would need steel and shotcrete. These predictions were supported by fact when the tunnel system was completed.

Load Characteristics of the Industrial Railroad

The industrial railroad has the following daily average load characteristics (include both the Toquepala and Cuajone operations): concentrates and blister copper, 4.5 kt; supplies, 2.3 kt; and silicious flux and other materials 907 t.

Tunnels

The system consists of five tunnels with a total length of 27,076 m and a net cross section of approximately 36 m². Tunnel data are given in Table 14.

Pipeline for Tailings Transportation

A system of 762-mm resin-reinforced fiberglass plastic pipelines was originally installed in four of the tunnels for transporting the Cuajone tailings. The R-5 tunnel, located south of Quebrada Simarrona, that is, past the point where the tailings from both concentrators mix, does not contain pipelines.

Although extensive and successful tests using Toquepala tailings had been carried out to determine the abrasion resistance characteristics of the plastic pipeline, it became necessary to replace the Cuajone tailings pipeline system. A steel-reinforced concrete flume was used to replace the plastic pipeline after the second year of operation when it became evident that the abrasion/flow characteristics of the Cuajone tailings exceeded the wear resistance of the plastic pipeline.

MAIN ROAD SYSTEM

The roads consist of permanent highways and access roads to the different areas.

Permanent Highways

Permanent highways have been built or improved for connecting the centers of operations, camps, etc. These permanent highways permit access to the Cuajone unit area from the Toquepala mine, from the city of Moquegua, and from the Andean highlands. A total of 123 km of permanent roads were built and 68 km of permanent highways were improved.

Access Roads

An extensive trail and road network was built during the construction phase of the project to serve the various sites and facilitate the supply of equipment and materials for

construction. Many of these roads have been kept in operating condition to provide access for inspection and maintenance purposes to pipeline, transmission lines, tunnel systems, and other installations.

TOWNSITES AND GENERAL SERVICE INSTALLATIONS

Permanent Townsites

Two permanent townsites have been built and a third substantially expanded to provide housing and other community services and facilities for the Cuajone operating personnel and their families. These new towns were constructed

in accordance with standards and requirements of the Peruvian mining code relating to housing, educational, and medical facilities. The permanent townsites are: (1) Villa Cuajone to house management and supervisory personnel, (2) Villa Botiflaca to house employees and workers, and (3) expansion of Ilo camp.

Villa Cuajone faces the Torata Valley and is located 18 km west of the Cuajone mine, 10 km from the Cuajone concentrator, and 30 km from the city of Moquegua (road distances), at an average elevation of 2700 m above sea level. Three- and four-bedroom houses eight-unit apartment buildings, and other housing units have been constructed for mar-

ried and single status personnel and for visitors. Villa Cuajone has adequate educational, social, and recreational facilities; a shopping center; police and fire stations; and ancillary community services.

Villa Botiflaca is located 8 km west of the Cuajone mine, 2 km from the Cuajone concentrator and 38 km from the city of Moquegua (road distances), at an average elevation of 3325 m above sea level. Eight- and 12-unit three-bedroom apartment family buildings and single status residence halls and dormitories have been constructed. Villa Botiflaca has adequate social and recreational facilities, a church building, movie house, shopping center, police and fire stations, bakery, laundry and dry cleaning plants, and other community services.

Ilo Townsite, which originally housed the personnel operating the Ilo smelter, the power plant, the seawater desalination plant, port, and the industrial railroad and other installations related to the Toquepala operations, has been expanded to house and provide adequate services for the new personnel required in the area as a result of the incorporation of the Cuajone unit.

Temporary Camps

Ten temporary camps and ancillary installations were built to house and provide necessary services to contractors' personnel during the construction phase of the project. A work force of about 6000 men used these facilities.

English equivalent: meter \times 3.281 = foot.

Cuajone Hospital

A 69-bed hospital located near the Botiflaca-Villa Cuajone road junction was constructed and it has been provided with the most modern medical equipment and comfort. The original Ilo hospital has been expanded.

General Service Installations at Cuajone

These comprise facilities that provide services to all operations in the Cuajone area, rather than to specific areas or operational functions. They consist, essentially, of the general office, operations office, industrial warehouse, time office, flammable material storage building, and the Cuajone airstrip.

SHOPS AND SUPPORT INSTALLATIONS

Mine Shops

An ample mine heavy duty shop has been built and equipped to repair and service large-size mining machinery and equipment. This shop consists essentially of machine welding, shovel, repair, tractor, and tire and truck sections.

Other support installations in the area are the explosive magazine, electrical shop, engine rebuild shop, and tank farms.

Concentrator Area Shops

The light duty and paint shops for the repair of automotive vehicles, built for use during the construction phase, continues in operation. Additionally, the concentrator area includes a small warehouse, a carpenter shop, and a light mechanical shop.

Ilo Area Shops

The Ilo port and smelter shops were enlarged to take care of the requirements for the Cuajone project in that area.

Industrial Railroad Shops

These comprise the expansion of the Toquepala industrial railroad maintenance shop and the construction of a mine locomotive shop at Cuajone.

Camp Maintenance Shops

Camp maintenance shops were built at Villa Cuajone and Villa Botiflaca and the Ilo camp maintenance shop was expanded.

Principal Temporary Installations

To satisfy the Cuajone project's construction phase needs, several temporary shops and ancillary installations were built in different areas of the project. The principal installations are the Ilo steel fabrication shop, tunnel shops, concrete batch plant, block plant, aggregate plant, carpenter shop, reinforced plastic fiberglass mortar pipe plant, and a large diameter steel pipe fabricating shop.

CONSTRUCTION CONTRACTORS

Fluor Utah Inc. was the general contractor for engineering and construction management. The project employed over 30 independent contractors—mostly Peruvian construction companies, some of which associated, under joint venture contracts, with internationally recognized building contractors. During its construction phase, Cuajone employed about 6000 workers.

9.6 The Chuquicamata Complex

ENRIQUE MOREL DONOSO

INTRODUCTION

Of the four divisions of the National Copper Corp. of Chile (CODELCO-Chile), the Chuquicamata complex is the largest mineral resource. It is located in the province of Loa, II Region, Antofagasta, Chile, 1600 km (994 miles) north of Santiago, the nation's capital. It is also 240 km (149 miles) northeast of the port of Antofagasta and 150 km (93 miles) east of the port of Tocopilla, between 2500 and 3000 m (8202 and 9843 ft) above sea level (Fig. 1). The most important populated zones in the area are Calama with 90,000 inhabitants and Chuquicamata with 17,000.

The climate in the region corresponds to marginal high altitude conditions, is extremely dry and rainless, except during the *Bolivian winter* which occasionally produces torrential rains between December and March. The average annual temperature is 22.8 °C, subject to seasonal and daily variations.

The complex is based upon a porphyry copper deposit, 14 km (9 miles) long from north to south, with an average width of 1 km (0.6 miles) from east to west, in which are to be found the areas known as *Chuqui Norte*, still unexploited, Chuquicamata, which is the principal area under exploitation, and immediately to the south, *Mina Sur*, also being exploited. The latter orebody is formed by the deposition of oxidized exogenous ore that gave origin to an exotic copper deposit 6 km (3.7 miles) in length from north to south.

The power required by the complex is obtained from two thermoelectric generating plants owned by the company. The most important, and the one that produces approximately 90% of the power used, is the Tocopilla Thermoelectric Plant located at the port. The remaining 10% is obtained from the Chuquicamata Thermoelectric Plant which generates low-cost energy by means of waste heat boilers that use the excess heat of the gases from the reverberatory furnaces in the smelter.

The water used by the complex comes from the Andes mountains, by means of two water supply pipelines for industrial water, 60 km (37 miles) and 70 km (43 miles) in length, and three supply pipelines for potable water 99 km (61.5 miles), 92 km (57 miles), and 108 km (67 miles) long, respectively. Through different retreatment and recovery systems, approximately 70% of the fresh water received is recirculated. The main systems are the sewer water treatment plant, tailings dam water recovery system; thickeners systems in the concentrator, recirculating system in the smelter; thermoelectric plant and substations.

Considering the history of the Chuquicamata complex, the magnitude of the deposit, the many technological changes, and the resulting projects developed during its exploitation, this is a very special mining project. Accordingly, the following points will be described: the history and geology of the deposit; project execution; description of operations; operations costs; and production and technology in the future.

THE HISTORY AND GEOLOGY OF THE DEPOSIT

History

Before the Incas conquered the region, it was inhabited by a small tribe of Indians who had descended from the

Aimarás and the *Quechuas*, who were known as the *Chucos*, hence the name *Chuquicamata*.

Archaeologists and historians think that aborigines of the area of Atacama were the first to use the copper from this region in the making of domestic utensils and weapons. It is believed that Diego de Almagro, on his return to El Cuzco after the invasion of Chile, used copper from Chuquicamata to reshoe his horses.

At the close of the last century, some of the copper veins near Chuquicamata were being exploited, in particular the *Zaragoza*, *Balmaceda*, *Angélica*, *Poderosa*, *Lérida*, and *San Antonio* veins. In 1910, Albert C. Burrage, a lawyer and financier from Boston, obtained information on the extent of the Chuquicamata deposit. After a thorough study, he then interested the Guggenheim Brothers in the project, who in turn founded the Chile Exploration Company in Chile on January 11, 1912. The evaluation of the deposit was then undertaken and very soon the figures justified accelerated mining development.

Mining operations began in 1915 with the extraction of oxidized ore, principally atacamite, antlerite, brochantite, and kioehnkite with approximately a grade of 1.75% Cu. Since 1952, copper sulfides have been mined, principally chalcocite, covellite, and chalcopyrite.

During its 67 years of operation, the mine has lived the history of the development of mining equipment, from steam shovels, rail mounted shovels, chain shovels, wooden hammer and rope drills, steam locomotives, etc., to the modern equipment presently in use such as electromechanical shovels with a capacity of up to 21.43 m³ (28 yd³), electromechanical trucks 231 t (255 st) and modern rotary drills. As the production of the mine reached certain sectors of the oxide/sulfide transition zone, the need arose for construction of a plant to treat the ore by flotation and fire refining methods. The new plant went into service in 1952 and gradually became increasingly important in the total production of fine copper, while production based on oxidized ore declined. By 1971, the exploitable reserves of the oxide minerals in Chuquicamata had been exhausted. To replace this type of ore and to take advantage of the existing facilities in the leaching plant, in 1970 the first ore from the Exotica mine (today known as Mina Sur) was processed as part of the production of the Chuquicamata mining complex.

In all these years of operation in the main pit of Chuquicamata, until June of 1982, the following quantities of ore have been extracted:

Material	Millions of st
Oxidized	505
Sulfides	518
Mixed	49
Waste	938
Total	2,010

The exploitation has given the excavation the form of a large elliptic amphitheater whose present dimensions are 3.5 km (2 miles) in length, 2.0 km (1.2 miles) in width at the top, and a depth of 476 m (1562 ft) from the highest point. At the present time, the copper sulfides exploited are chalcocite, covellite, chalcopyrite, etc., and only a small reserve

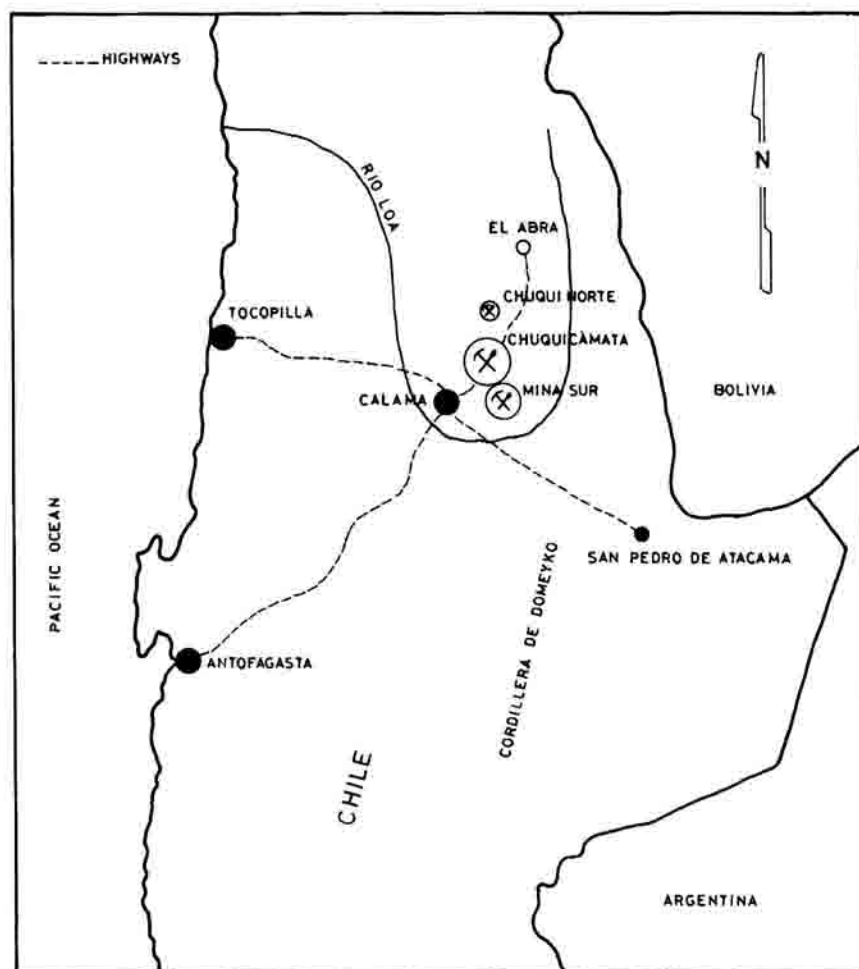

Fig. 1. The Chuquicamata complex and its location, National Copper Corporation of Chile (Codelco-Chile).

of oxidized ore remains. It is also worth noting that the deposit contains other useful elements such as molybdenum in the form of sulfide (molybdenite), gold and silver, the recovery of which, as byproducts, is economically profitable.

In 1952, for the purpose of finding the northern limit of Chuquicamata, and because of the need to look for new reserves of oxidized ore, a drilling program using churn drills was carried out on an east-west profile every 500 m (1640 ft) up to 10 km (6.2 miles) north of the Chuquicamata pit. This led to the discovery of the mineralized zone called *Chuqui Norte*.

In 1963, drilling was carried out on the spent oxide dumps to the south of Chuquicamata to investigate the flow of solutions of in situ leaching tests. These drill holes discovered the exogenous deposit now exploited and known as *Mina Sur*.

Geology

The Chuqui porphyry copper is a porphyritic body of granodiorite vein type, 14 km (8.7 miles) long with a mean width of 1 km (0.6 miles) completely mineralized, but with a nucleus of greater mineralization in Chuquicamata and Chuqui Norte. The estimated age is between 32 and 34 million years.

The deposit is formed by magmatic porphyry that probably began to develop during the Lower Paleozoic period and during the latest stage of development in the Middle Tertiary, together with a process of potassic alteration, the first mineralizing phase took place, with the addition of chalcopryite, bornite, digenite, pyrite, and a slight amount of molybdenite. After the mineralizing phase, the process of hydrothermal alteration took place. Here we must distinguish between 1) the early hydrothermal phase, with limited sericite quartz alteration, characterized by the addition of a maximum of molybdenite, together with chalcopryite and pyrite, 2) the main hydrothermal phase, with a new addition of pyrite, chalcopryite, and some enargite, and 3) the later hydrothermal phase that added pyrite, enargite, sphalerite, galena, and tetrahedrite.

Later on, during the Pliocene, large amounts of rain water formed enriched bodies in each sector. In the west sector of Chuquicamata, the water was able to penetrate to great depths [over 1000 m (3280 ft)] through the principal faults, forming an upper leached zone and beneath that, an important zone rich in chalcocite and a still lower zone rich in covellite.

To the east, the rock is less fractured and presents potassic alteration, so that the copper in the solutions was neutralized near the surface in the form of mineral oxides and less important zones rich in chalcocite and covellite were developed below.

PROJECTS AND DEVELOPMENT PLAN

The development plant at Chuquicamata is revised annually to bring it up-to-date according to present and expected future conditions. Within this permanent process of planning and operations, some important projects have been concluded recently, others are being carried out, and others are still under study to be put into effect in the coming years.

Among those that have been completed recently, the following should be noted: (1) expansion of the concentrator complex that consisted principally of increasing the treatment capacity by 26 kt/d (28,660 stpd), at an investment of over US\$ 100 million, and (2) construction of a molybdenite roaster plant, with a capacity of 5.5 million kg/a (12 million lb per yr), costing approximately US\$ 20 million.

Among the projects currently being executed, the most important are (1) expansion of the thermoelectric plant at Tocopilla by the addition of a 72 MW unit (N°12) at a cost of US\$ 70 million; (2) a new primary crushing station with the capacity to treat up to 9600 t/h (10,582 stph), at a cost of US\$ 100 million; and (3) development of the concentrate smelter (first stage), consisting of a group of related subprojects, including expansion of dryer capacity, enlargement of converter bay, installation of a modified converter of the Teniente type, a gas recovery system, an oxygen plant, and improved storage and handling of concentrate. The investment in this phase amounts to US\$ 70 million.

The following projects have been approved for the next few years: (1) expansion and rebuilding of the refinery to increase production capacity from 370 kt/a (407,855 stpy) to 630 kt/a (694,456 stpy); (2) oxide tailings *ripios*, dump leaching and solvent extraction plant, to achieve a production rate of 200 t/d (220 stpd) of fine copper by 1988; (3) heap leaching to replace vat leaching, to achieve production of 140 t/d (154 stpd) of fine Cu. This technological change will permit significant reduction in production costs in the oxide line. This project also includes a solvent extraction plant with a capacity to treat 2000 m³/h (1529 yd³ per hr) of solution. Expansion of the Tocopilla thermoelectric plant with two more units (13 and 14) of 72 and 38 MW, respectively, is also planned.

The basic objectives of the projects included in the Chuquicamata development plan are (1) to maintain the copper production capacity in the sulfide line, compensating for the lower ore grade and the increased hardness of the ore by means of expansions in the mine and the concentrator; (2) to develop the oxide line to a level of approximately 200 kt (220,462 st) of fine Cu per year; (3) to reduce costs and increase efficiency by improving processes and the incorporation of new technologies; and (4) to increase the added value of the products, in particular by producing electrowon cathodes from surplus concentrates that are sold or toll smelted today.

The plans of the Chuquicamata division are analyzed from the technical and economic viewpoints in the different areas as an interrelated whole by means of a complex computer model. Thanks to this model, it is possible to simulate the multiple alternatives in a short time, which permits the selection of the best plan, and to change some of the subalternatives should it be required by conditions imposed by the market or by those of a financial nature.

DESCRIPTION OF OPERATIONS

The Mine

Mineral Exploitation: The exploitation of the Chuquicamata mine is by the open pit method, which system will be used for at least the next 25 years.

The present dimensions of the excavation are 3500 m (11,483 ft) long, 2000 m (6,562 ft) wide, and 476 m (1562 ft) deep. There are 21 benches where drilling, blasting, loading, and transportation of the ore and waste rock are carried on. These benches are 24 and 26 m (78.7 and 85 ft) high (double benches) in waste and 13 m (43 ft) (single benches) in ore. The final dimensions of the pit will be 4100 m (13,451 ft) long, 2650 m (8,694 ft) wide and 986 m (3,235 ft) deep.

A basic exploitation plan for a 25-year period, feeding 96 kt/d (105,822 stpd) of ore to the concentrator, implies the moving of 2493 Mt (2,748 million st) of material with an overall ratio of waste plus low grade ore to ore of 1.89. The fine copper production level decreases from 1300 t/d (1433 stpd) at present to 800 t/d (882 stpd) by the end of

the period, due to the reduction in ore grade as a result of the change from the present secondary enriched zone to the primary zones of the deposit. Chalcopyrite increases progressively while chalcocite and covellite decrease. The same grade change occurs with the molybdenum in the ore.

The mine next to Chuquicamata, Mina Sur, is exploited with benches 13 m (43 ft) high. The present dimensions of the pit are: 1500 m (4,921 ft) long, 1200 m (3937 ft) wide and 195 m (640 ft) deep. The oxidized ores are leached in vats which were used for the processing of oxides from the Chuquicamata pit. The basic production level of fine copper, 95 t/d (105 stpd) requires the handling in the next 22 to 24 years of 450 Mt (496 million st) in order to achieve the final pit.

The Chuquicamata Pit: Usually work goes on six days a week, in three 8-hr shifts per day, and Sunday is assigned to maintenance and special repairs to roads and access to the dumps, special earth moving jobs, and the relocation of heavy equipment and machinery. Also the preventive maintenance and major repairs on equipment and the primary belts in the crushing system are done on Sundays in order not to interrupt productive work during the week.

The Chuquicamata mine has a crusher-belt system located in the pit for handling ore. The main piece of equipment is an Allis-Chalmers gyratory primary crusher 1.37×1.88 m (54×74 in.) with a capacity of 5 kt/h (5512 stph) and a system of conveyor belts in two sections of 1524 mm (60 in.) wide and a total of 1830 m (6004 ft) in length, which transport the ore through a tunnel and which discharge the storage pile (120 kt capacity) at the concentrator.

Drilling—The first step of exploitation is the drilling of blast holes to a depth equal to the height of the bench plus 2 to 3 m (6.6 to 9.8 ft) subdrilling. The drilling is done with electromechanical rotary drills, eight Bucyrus Erie units, model 61-R, and one Gardner Denver model GD-60, powered by 5,000 V obtained from an aerial loop installed in the mine. Tricone bits of 279 and 311 mm (11 and $12\frac{1}{4}$ in.) diameter, with tungsten carbide inserts of different brands are used. The drilling pattern is designed with vertical holes laid out in rectangles or similar pattern, spaced at an average of 7×9 m (23×29.5 ft).

The average length of drill hole achieved daily is 1480 m (4856 ft), or the equivalent of 217 m/working shift/machine, with approximately 37 400 m (122,703 ft) drilled per month. The cost of drilling is approximately 5.4% of the mine's total operating cost. Since the drill bits represent the greatest share of this cost, strict statistical control of yield and cost per bit per meter drilled is maintained.

Blasting—Blasting is carried out according to a plan determined by the planning and operations engineers and represents 16.4% of the mine's total operating cost.

The average explosive load for the mine is approximately 0.215 kg (0.474 lb) of explosive per ton blasted; 60% of the explosives are nitrocarbonitrates and the rest aqua-gels.

Nearly 3700 t/d (4079 stpd) of rock requires secondary blasting, for which three boom drills and one hydraulic rock-breaking hammer are used.

Loading—The total daily production of the mine is 300 kt (331,000 st) with a ratio of waste (including low-grade mineral) to ore of nearly 1.8. The loading is done by fourteen electromechanical shovels with a bucket capacity that varies between 9.17 (12 yd^3) and 21.41 m^3 (28 yd^3).

The shovels used are Bucyrus Erie 190-B (1) and 280-B (2), Komatsu-Bucyrus 280-KB (6) and P&H 1,800 (5). To support the loading operation, 7.65 m^3 (10 yd^3) and 9.17 m^3 (12 yd^3) capacity Caterpillar 992 and Clark Michigan 475

front end loaders are used. The loading phase represents approximately 13.6% of the mine's total operating cost. The average shovel production is 12 420 t/working shift/machine.

Transportation—At the present time, the transportation of material from the mine, whether to the crushing stations, storage piles, or waste dumps, is carried out solely by trucks. The fleet includes 90 units whose capacity varies between 109 t (120 st) and 231 t (225 st). The makes of truck used include Wabco 120-B and C, 170-C and D and 3200-B, Térex 33-15-B and Euclid R-170s.

The performance of the 154 t (170 st) units (57% of the total fleet) is approximately 1250 t-km/working hour, for an average haul distance of 4.5 km (3 miles).

It should be noted that since 1979, a computerized dispatch system controls the trucks and this has permitted substantial improvement in the operation, an increase in the effective usage of the equipment and a cost decrease. It also permits continuous control and homogenization of the ore blend sent to the plant through the control of the copper grade, molybdenum, and arsenic content. The cost of transportation is approximately 48% of the total operating cost of the mine.

Auxiliary Equipment—For production support jobs, there are 25 Caterpillar tractors, 17 rubber tired tractors, 9 bulldozers, and 6 front loaders of different brands and types. There are also 840 m^3 (52 yd^3) water trucks for sprinkling the roads, fuel trucks, compressors and personnel transport vehicles. The operation of the auxiliary equipment represents about 13.6% of the total operating cost.

The Mina Sur Pit: At present, Mina Sur moves 40 kt/d (44,092 stpd) of material, with a waste to ore ratio of 2.7. The equipment used includes one Bucyrus Erie 60-R drill, four Bucyrus Erie 190-B (2) and 280-B (2) electromechanical shovels, a fleet of 16 offroad trucks—8 Lectra-Haul M-100 and 8 Wabco 120-Bs—and 12 pieces of auxiliary equipment.

The ore is transported by truck to a primary crushing station outside the pit. Here an Allis-Chalmers 1.37×1.88 m (54×74 in.) gyratory crusher is used. The ore is then transported on a 2.6 km (1.6 miles) long, 1.22 m (48 in.) wide conveyor belt to the storage piles at Chuquicamata. The capacity of the system is 2500 t/h (2756 stph).

Chuqui Norte: This ore body is the north extension of the Chuquicamata deposit and contains low-grade copper oxides and sulfides covered by 80 m (262 ft) of overburden. The exploitation of this area in the future is under study.

Specific Projects

Bank K-1 Crushing Station—At the beginning of 1984, a new crusher/conveyor belt system was put into operation in the Chuquicamata pit to replace the old one.

It's advantages are shorter distances for truck transport in the mineralized section and an increase in crushing capacity up to 156 kt/d (171,961 stpd). The exploitation of the zone where the old system was will provide excellent quality ore and a low waste to ore ratio.

This new system includes two Allis Chalmers 1.52×2.77 m (60×109 in.) gyratory crushers and two parallel conveyor belts 1.83 m (72 in.) wide and approximately 2.5 km (1.6 miles) long. In 1981, construction began on the conveyor tunnel out of the pit. The tunnel is 5.7×9.1 m (18.7×30 ft) in section by 2340 m (7677 ft) long, with a 15.8% gradient for approximately 1500 m (4921 ft) and a 1.7% gradient for the remainder.

The Plants

Concentration: In the concentration plant, the flotation of sulfide ore from the Chuquicamata pit produces copper concentrate that is then sent to be smelted at the smelter. There is also some market for copper concentrates of approximately 38 to 40% Cu.

On the other hand, molybdenum concentrate (54% Mo) is obtained as a byproduct. This is packed in drums and sent for toll roasting, sale, or to the division's Roaster Plant.

Ore dressing is carried out in this area in various plants, through which the ore is submitted to size reduction stages and collective and selective flotation to obtain copper and molybdenum concentrates as final products.

The following is a description and flow chart of the five most important stages.

Crushing Plant—The size reduction stage begins in an Allis-Chalmers 1.37 m (54 in.) gyratory crusher at the mine, which delivers material of less than 0.20 m (8 in.) to a storage pile.

The material extracted from the upper benches of the mine is sent directly to the plant's primary crusher [Traylor 1.5 m (60 in.)]; the product is merged with the ore from the storage pile and together is sent to the coarse ore storage hopper [under 0.2 m (8 in.) ore] which has a capacity of 35 kt (38,581 st).

The secondary and tertiary crushing installations have a treatment capacity of 102 kt/d (112,436 stpd) and are divided into five sections. In each section the material from the coarse ore storage feeds a double deck Tyler F-900 vibrating screen. The ore under 12.7 mm (0.5 in.) is added to the final product of the plant while material coarser than 38 mm (1.5 in.) feeds to a standard Symons 2.1 m (7 ft.) crusher. The output from this crusher, together with the intermediate product of the Tyler F-900 screen feeds to four Tyler F-600 vibratory screens.

The material over 12.7 mm (0.5 in.) from these screens is reduced in two short head Symons 2.1 m (7 ft.) crushers and is added to the material under 12.7 mm (0.5 in.) forming the final fine product 8% + 12.7 mm (0.5 in.), which is sent to the fine ore storage bins of the concentrate. To assure a continuous ore supply, there is a fine ore reserve pile, with a 33 kt (36,376 st) capacity. Fig. 2 illustrates the crusher plant flow.

Concentrator Plant—This plant has twelve primary wet grinding mill sections, each of which is fed by two adjustable-speed belts. In each section, the fine ore is fed to a Marcy 3.1 × 4.3 m (10 × 14 ft) rod mill that in turn feeds two Marcy 3.1 × 3.7 m (10 × 12 ft) ball mills, each of which operates in closed circuit with a battery of Krebs D-20 hydrocyclones.

The overflow from the cyclones, at 28% + 212 μ m (65 mesh), is fed to primary flotation. There are 12 flotation sections, seven of which are made up of Agitair N°120 cells. Section N°3 consists of a row of six Agitair N°120-A cells and a row of seven Denver DR-300 cells. Wemco 14.16 m³ (18.5 yd³) cells have been installed in section N°7. The original Agitair N°48 cells in the rest of the sections are being replaced by Agitair N°120 cells.

The primary tailings flow by gravity to six 91 m diameter (300 ft) thickeners, whose underflow of 52 to 55% solids is sent to the tailings drain. Previously, in two tailings retreatment plants, some of the sulfide tailings have been recovered. The water recovered from the overflow of the thickeners is recirculated to the concentrator. The primary concentrate from each of the primary flotation sections is thickened to 45% solids in a Dorr-Oliver 24 m (80 ft) diameter thickener.

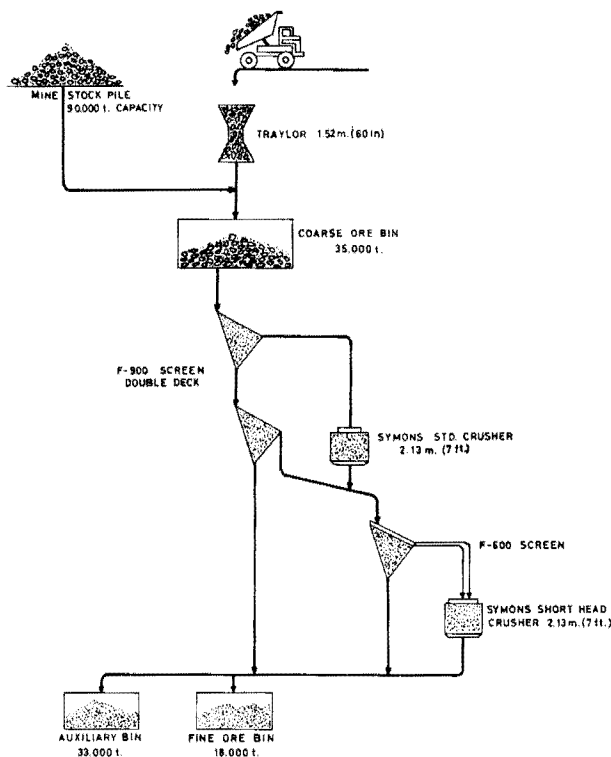

Fig. 2. Crushing plant, 102 kt/d capacity.

The underflow is reground in two Marcy 1.8 × 3.7 m (6 × 12 ft) regrind ball mills that operate in closed circuit with a battery of four Krebs D-10 cyclones. The overflow of the cyclones, at 15 to 17% solid and 80 to 90% -45 μ m (325 mesh), is fed to two rows of 14 Agitair N°60 cells for cleaning. The concentrate from here feeds the recleaning circuit that consists of 12 rows of 20 Agitair N°48 cells.

The collective Cu-Mo concentrate is obtained from the first six cells of each row. The concentrate collected in the following four cells is recirculated to the feed end of the circuit. The tailings of these four cells and the tailings of the cleaning flotation feed the cleaning scavenger flotation cells (10 cells) from which a concentrate is obtained. After thickening in an Eimco 30.5 m (100 ft) diameter thickener, this concentrate is reground in two Marcy 1.8 × 3.7 m (6 × 12 ft) ball mills that operate in closed circuit with one battery of Krebs D-6 hydrocyclones each. The product is recirculated to the second bank of four cells. When the scavenger tailings reach over 9.6% Fe content, they are sent to a small pyrite recovery plant. The scavenger cells tailings are added to the primary tailings. The collective Cu-Mo concentrate is then sent to two Eimco 45.8 m (150 ft) diameter thickeners operating in parallel. The underflow of these thickeners, after dilution with fresh water, goes to a third thickener similar to the previous ones. The 60% solids underflow of this last one feeds the molybdenum recovery plant. Fig. 3 illustrates a flow diagram of the concentrator plant.

Expansion of the Concentration Plant—The expansion of the concentration plant was completed at the beginning of 1982, with an increase in ore treatment capacity to 96 kt/d (105,822 stpd). This plant has three wet grinding lines. Each line consists of one Marcy 4.1 × 5.5 m (13.5 × 18 ft) rod mill and one Marcy 5 × 6.4 m (16.5 × 21 ft) ball

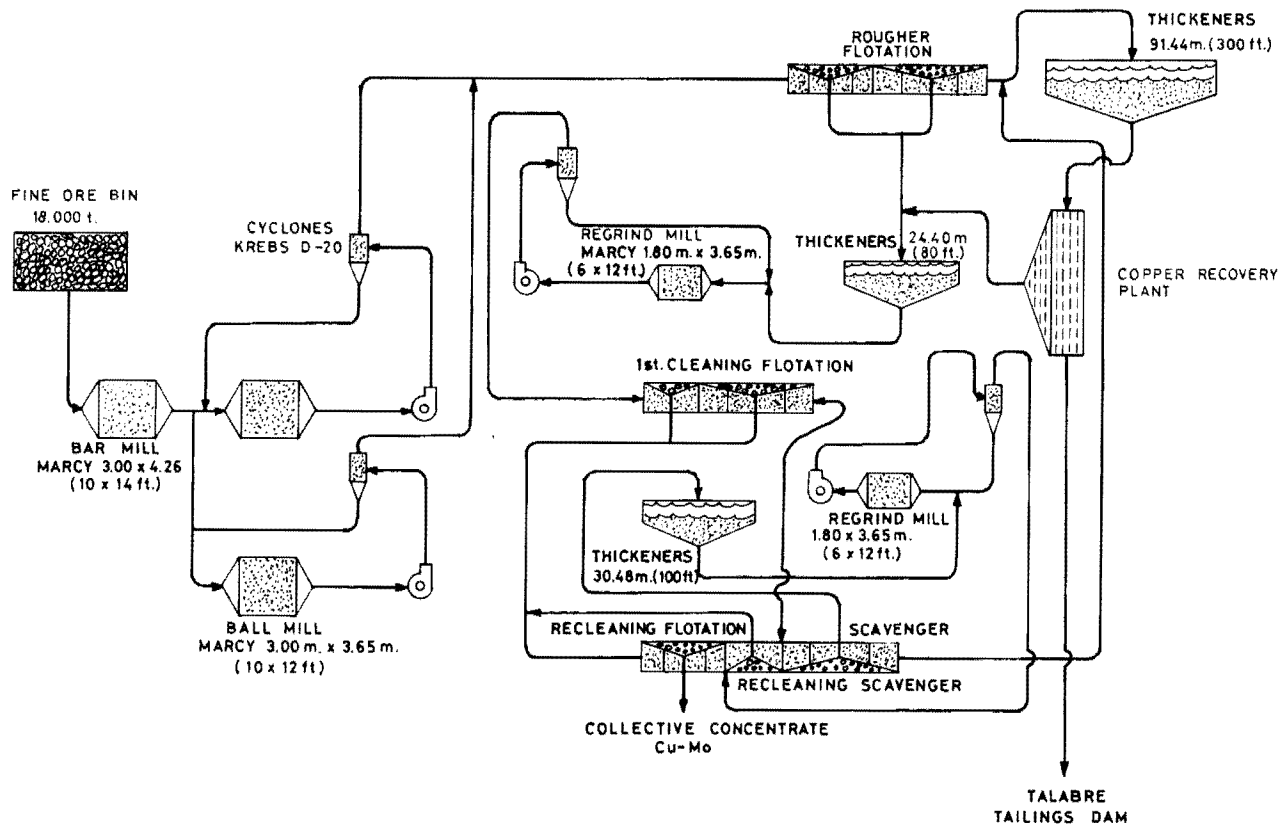

Fig. 3. Concentration plant, 70 kt/d capacity.

mill that operate with a battery of six Krebs D-26 hydrocyclones.

The overflow of the cyclones from the three lines is sent to a distributor that feeds three rows of 15 Denver 14.16 m³ (500 ft³) primary or rougher flotation cells. The primary concentrate produced is dumped to the battery of hydrocyclones of the regrinding circuit (Krebs D-15). The underflow is distributed to two Marcy 3.1 × 3.7 m (10 × 12 ft) ball mills. The overflow is sent to the cleaning circuit, formed by two rows of 13 Denver DR-300 [8.5 m³ (300 ft³)] cells. The cleaner concentrate is obtained from the first five cells, while the concentrate from the three middle cells is added wholly or partially to the cleaner concentrate or to the scavenger concentrate, obtained from the last five cells. The primary and scavenger tailings are sent to three tailings thickeners 99 m (325 ft) in diameter.

The cleaner concentrate feeds the recleaning circuit that is formed by a row of 13 Denver DR-300 [8.5 m³ (300 ft³)] cells. The collective concentrate is obtained from the first five cells and is added to the collective concentrate produced in the old plant. The concentrate from the three middle cells may be added totally or partially to the collective Cu-Mo concentrate or to the recleaning-scavenger obtained from the last five cells. These are also fed by the scavenger concentrate, after regrinding and classification in a closed circuit formed by a Marcy 1.8 m × 3.7 m (6 × 12 ft) ball mill and a battery of Krebs D-6 cyclones. The recleaning-scavenger re-feeds the recleaning flotation and the tailings re-feeds the scavenger flotation. The flow chart of the expansion of the concentration plant is shown in Fig. 4.

Molybdenum Recovery Plant—The collective Cu-Mo concentrate, after the two thickening stages described previously, is diluted to a solids content of 38 to 40% by weight and conditioned to a predetermined pH before being distributed to the four primary flotation rows. Each primary flotation row is made up of 20 Agitair N°48 cells, arranged in five banks of four cells each. The depressor reagent is added at the head of each row.

The primary tailings or general tailings of the plant are sent to the copper concentrate filter plant. The primary concentrate at 10 to 12% solids and a molybdenum grade that fluctuates between 7 and 15% feeds the cleaner flotation circuit. The cleaner flotation is carried out in two rows of 12 Agitair N°48 cells, arranged in three banks of four cells each. The tailings of this stage are sent to the collective concentrate thickeners and thus return to the circuit.

The cleaner concentrate is sent to a Dorr Oliver thickener 15.2 m (50 ft) in diameter. The underflow of this thickener, at 50 to 55% solids, is sent to two 250 m³ (8829 ft³) storage tanks, where the pulp is diluted to 25% solids before being fed to the second cleaner flotation.

The second cleaner flotation consists of two rows of 18 Agitair N°48 cells, arranged in a first bank of four cells, a second bank of six cells, and a third bank of eight cells. The depressor reagent is added at the head of each row and to each second bank. The tailings of the second cleaning are added to the feed of the first cleaner flotation.

The second cleaner concentrate feeds to a row of 18 Agitair N°48 cells, arranged in three banks of four, six, and eight cells each, where the third cleaning takes place. The

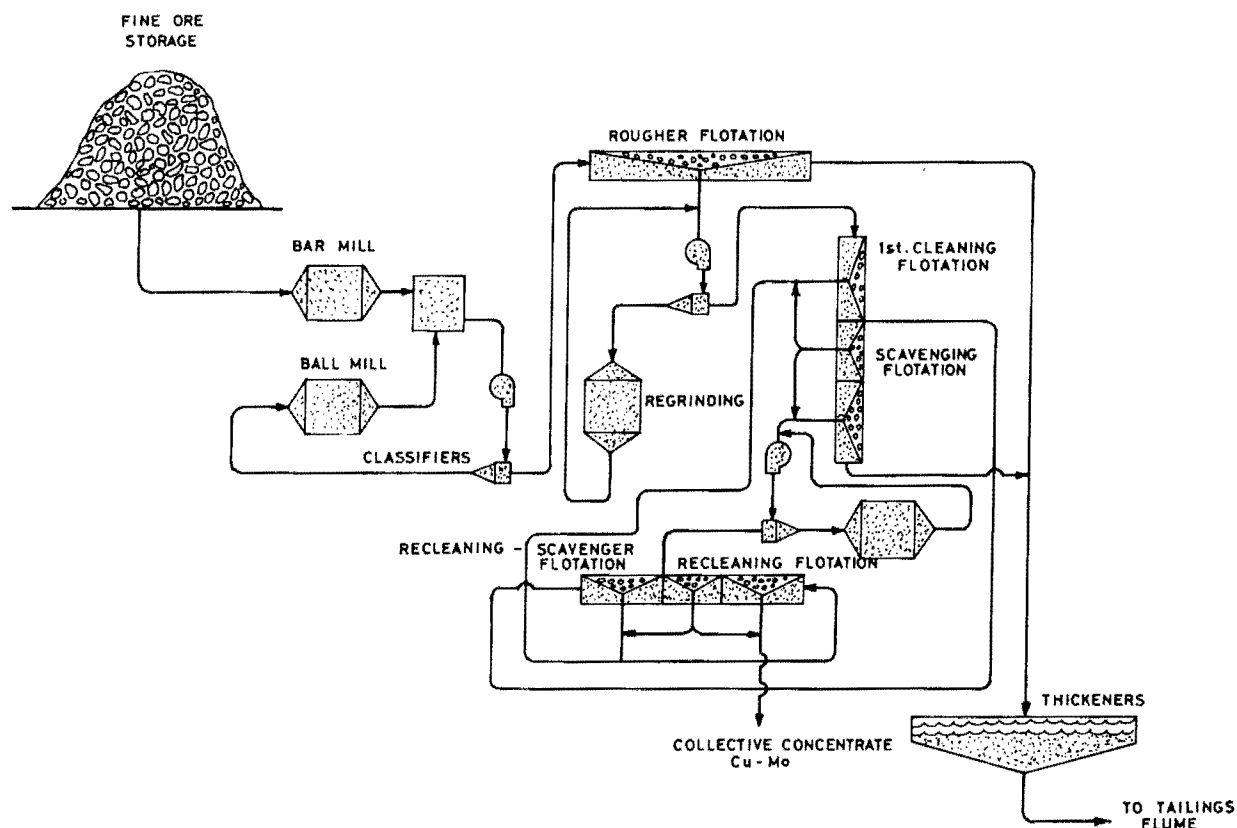

Fig. 4. Concentration plant expansion, 26 kt/d capacity.

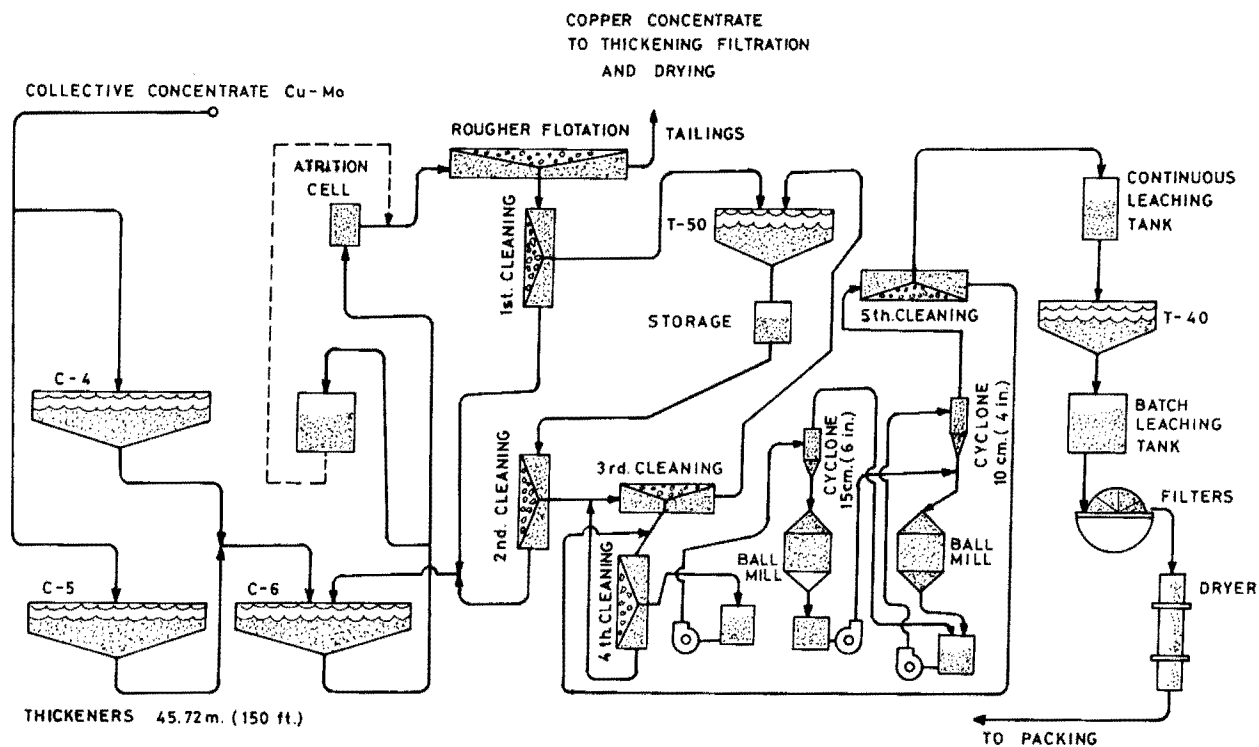

Fig. 5. Molybdenum recovery plant.

tailings of this stage, at approximately 10 to 15% solids, are added to the first cleaner concentrate. The concentrate, at 14 to 16% solids, is sent to a fourth cleaner flotation.

The fourth cleaner flotation is carried out in a row of 12 Agitair N°48 cells, arranged in two banks of four and eight cells each. The tailings are added to the second cleaner concentrate. The concentrate, at 16 to 20% solids, is sent for regrinding and classification in four Marcy 1.2 × 2.4 m (4 × 8 ft) ball mills, and the classifiers overflow goes to a distributor that feeds the fifth cleaner flotation.

The fifth cleaner flotation is performed in two banks of six Denver N°24 — 1.4 m³ (50 ft³) cells. The tailings of this stage are added to the third cleaner concentrate. The fifth cleaner concentrate, at 16 to 20% solids, is deposited in a box that feeds two 9 700-L (2562-gal) tanks arranged in series where continuous leaching takes place.

The pulp remains in the set of tanks for 1.5 hours and is then sent to a Dorr Oliver 12.2 m (40 ft) diameter thickener. The underflow of this thickener at 50 to 55% solids, is distributed to one of four batch leaching tanks, 4.9 m in diameter × 6.1 m high (16 × 20 ft) where the copper content is lowered to less than 0.15%. The underflow of each tank is diluted to 45% solids, and sent to an Eimco 8-disc 1.2 m (4 ft) diameter filter. The cake obtained from this filter is repulped with the addition of water and steam, and then sent to a second Dorr Oliver 1.8 m (6 ft) diameter filter. A final cake (25% humidity) is obtained and sent to one of the two drying tubes by means of helical conveyors. The drying tubes operate on superheated steam. Their capacity is 63.5 t/h (70 stph) and 45.3 t/h (50 stph), respectively.

The concentrate obtained at the discharge of each drying tube, with humidity between 0.5 and 2%, is stored in a bin. Part of the concentrate is packed in drums for shipment and the rest is transferred to the molybdenite roasting plant. Fig. 5 illustrates the flow of the molybdenum recovery plant.

The Molybdenite Roasting Plant—This plant has been designed to roast 5 443 109 kg (11,999,799 lb) of molybdenum concentrate per year to produce Molybdc oxide technical grade.

The process begins with the storage of molybdenum concentrate in two bins, which can either feed the area where concentrate is packed in drums, or to a 6.6 t/h (7.3 stph) capacity pneumatic conveyor system to the roasting plant. The transport of concentrate is performed in the dense phase and air is delivered by a 93.21 kW compressor. The concentrate is received in two 500-t (551-st) silos.

The roasting furnace is fed with Mo concentrate by means of a screw conveyor and a bucket elevator system. The bucket elevator is also fed by the return of dust from the gas treatment system. The roaster is a 6.6 m diameter (21.5 ft), 12-story Nichols oven, with a treatment capacity of 16.3 t/d (18 stpd) of molybdenum concentrate.

The roaster is equipped with kerosene combustion burners on the different floors and LPG is used for initiating firing. The gas from the roaster feeds to a cleaning system, which consists of an indirect cooler, a secondary cooler, two multicyclones in series, a multicyclone blower, a dry electrostatic precipitator, and a blower. The dust recovered in this system is returned to the roaster by a screw conveyor.

The molybdenum oxide, at a temperature of 482 °C (900 °F) at the roaster discharge, is fed to a size reducer to eliminate any clinker produced in the roasting process. Once a uniform size of material is obtained, it is fed to a cooler where the temperature of the oxide drops to 93 °C (200 °F). The cooled material is transferred to a bucket elevator that feeds a classifying screen. The oversize material is sent to a

size reducer and returned to the screen. The undersize material is sampled, weighed, and transported by screw conveyor to one of nine storage bins. The packing facilities provide for packing the product in 10-kg (22-lb) cans or 115-kg (254-lb) drums. Fig. 6 illustrates the flow of the molybdenite roasting plant.

Concentrate Smelting: The smelting of copper concentrate, because of the characteristics and processes used, is defined as traditional smelting. The most important equipment and installations used at the present time are described in the following sections.

Concentrate Drying Ovens—The filtered copper concentrate coming from the filter plant reaches the drying units in the smelter by conveyor belts. These units (13) are cylindrical rotating furnaces, with a total capacity of 203 t/h (224 stph).

Once the humidity of the concentrate has been reduced to adequate limits (6 to 8%), it is carried by conveyor belts to storage and the charge preparation facilities that consist of three beds with a charge capacity of 8500 t (9370 st) each.

Reverberatory Furnaces—These units, four in total, have the following characteristics:

	Reverberatory Furnace Nos. 1, 2, 3	Reverberatory Furnace No. 4
Length (m)	39.62	36.58
Width (m)	9.14	10.67
Height (m)	3.73	4.16
Bed area (m ²)	235.25	245.10

Here the prepared charge or *green charge* (concentrate + flux + circulating charge) is smelted, producing three products: matte, slag, and gases.

Matte is the rich copper product that continues to be processed. The slag, since it is a material with a Cu content of less than 1% is discarded and is transported to dumps by railroad in 6.37 m³ (225 ft³) ladle cars. The gases, from which the heat and dust are recovered, are eliminated through a 91.44 m (300 ft) stack that can evacuate approximately 450 000 Nm³/h.

In order to take advantage of the heat from the gases, each of the reverberatory furnaces has two boilers that can generate about 20 t/h (31 stph) of superheated steam used in the Chuquicamata thermoelectric plant for power generation, representing a production of 12,600 J (3.5 MW).

The dust recovered is stored for future recirculation. Smelting is achieved by a combination of air-oil burners or regular horizontal burners (AFB) and vertical oxy-fuel burners (OFB) that use No. 6 oil (Bunker C) as fuel. This last type is controlled by a computerized system in a centralized control room or console where the corresponding flows are regulated and verified.

Converter Furnaces—The matte, rich in copper, as it comes from the smelting units, is processed in conversion furnaces (7 Peirce Smith) that have the following characteristics:

	Converters Nos. 2-7	Converter No. 1
Length (m)	10.671	12.195
Diameter (m)	3.963	3.963
No. of nozzles	52	55
Air Feed:		
a) pressure (kPa)	138	138
b) flow (m ³ /min)	650-800	650-800
Production capacity (t/d)	200-250	200-250
Nozzles punding	mechanical	mechanical

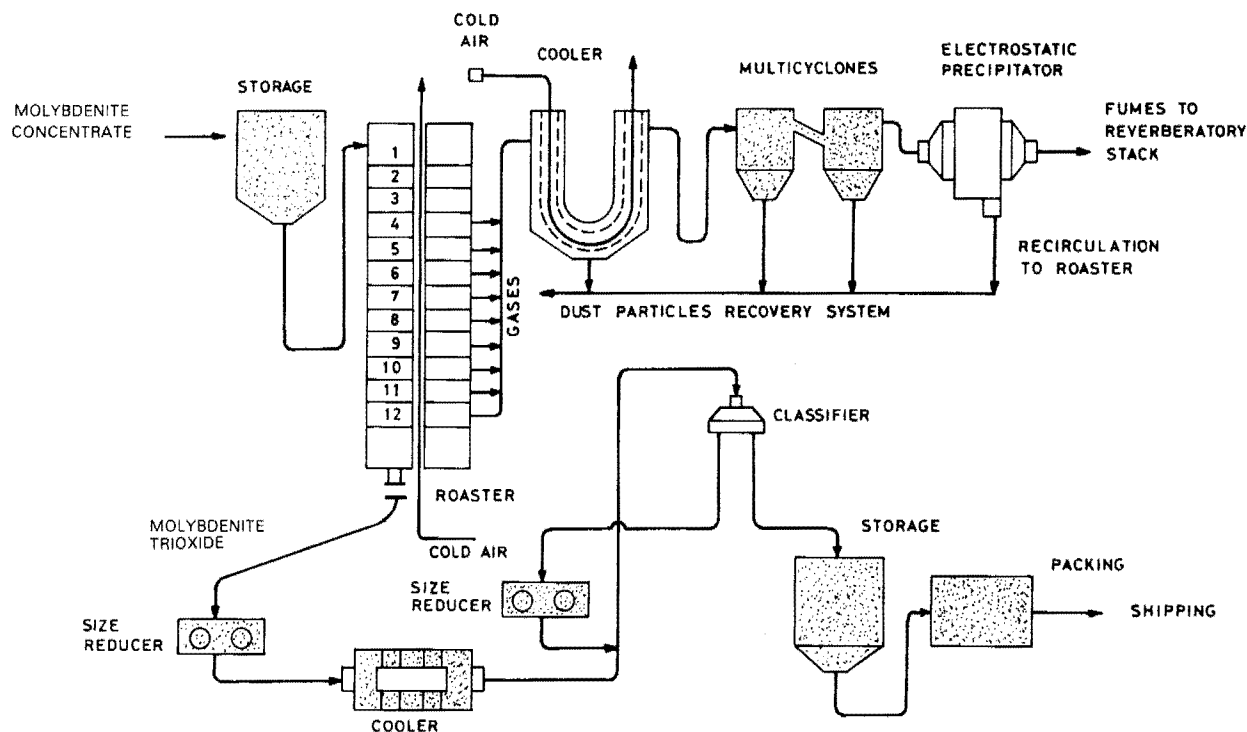

Fig. 6. Molybdenite roasting plant.

In these units, by the blowing of air through the nozzles and silica as flux, iron and sulphur are eliminated from the matte, converting it into blister copper after 6.5 to 7 hours of processing.

Modified Teniente Type Converter—This is a smelting conversion unit that is fed with concentrate, flux, and matte. Conversion takes place to white metal by blowing oxygen enriched air.

The gases generated are used in the production of sulfuric acid and the slag obtained in the process is sent to the treatment plant to recover the copper it contains.

The principal characteristics of the equipment are as follows:

Length (m)	18.29
Diameter (m)	4.04
No. of nozzles	67
Air Feed:	
a) pressure (kPa)	138
b) flow (m ³ /min)	650-800
c) oxygen enrichment (%)	30
Concentrate feed, t/d (dry)	700
Matte feed, t/d	655
White metal produced, t/d	750

Overhead Cranes—The handling of liquids and secondary materials in the conversion bay is performed by five cranes that have a central hook with a capacity of 92 t (10 st) and two auxiliary hooks with a 23-t (25-st) capacity each. This equipment handles ladles of 3.5 to 7.2 and 9.2 m³ (325 ft³) and metal bins for the transport of copper scrap.

Refining and Casting—The blister copper obtained from the converters is transported in a liquid state to the refining furnaces (6), which have the following characteristics:

Length (m)	7.62
Diameter (m)	3.96
No. of nozzles	6
Capacity (t Cu/charge)	200-220
Casting system	automatic weighing

In these units, to obtain a product of 99.6 to 99.8% Cu content, the copper is submitted to a process of fire refining, consisting of two stages: (1) oxidation by air under pressure; and (2) reduction using kerosene atomized by steam or by eucalyptus logs as the reduction agent.

Casting Wheels—This equipment (3), one unit serving two refining furnaces, has the following characteristics:

—Diameter (m)	12.58
—No. anode molds	26
—Casting speed (t Cu/h)	40

The copper is casted in the form of anodes that weigh 365 kg (805 lb) (commercial anodes) and 385 kg (849 lb) (initial plate anodes). After the elimination of possible burrs, the anodes are sent to railroad cars to the electrolytic refineries. Fig. 7 shows the flow of the concentrate smelter.

Refineries: The electrometallurgical processes in this area are concerned with the electrorefining and electrowinning of copper and the treatment of anode slimes. These processes are carried out in the following installations: refinery No. 1 (E.R. No. 1); refinery No. 2 (E.R. No. 2) and the noble metals plant.

The electrolytic refineries in Chuquicamata have a production capacity up to 32 kt/month (35,274 st per month) of copper in the form of electro-refined cathodes (15,500 electro refinery E.R. No. 1 and 16,700 electro refinery E.R. No. 2) and up to 4 kt/month (4,409 st per month) of elec-

trowinning copper. Ore metal production is about 80-100 t/a (88-110 stpy).

Electrolytic Refinery No. 1—This refinery was initially designed for electrowinning. With the depletion of oxidized minerals and the increase of sulfide ore, the electrowinning circuits have been modified to electrorefining ones.

The electrorefining area includes circuits Nos. 3, 4, 5, 6A and 6B with a total of 786 cells. The electrowinning area includes circuits Nos. 1, 2, and 7 with a total of 318 cells.

Electrolytic Refinery No. 2—This refinery has all the technical advances known at the time of its construction in 1969. It has been adapted and modernized to maintain the quality and cost of cathode production. Originally designed to produce 13,500 t/month (14,881 st per month), now it produces 16,500 t (18,188 st) monthly.

Refinery No. 2 is divided into three bays, two lateral bays for production, and one center service bay that houses the entire hydraulic and thermal system (pumps, tanks, exchangers, etc.) designed for the circulation of the electrolyte, for heating it, and for the evaluation of anode slimes. Circuits 10, 11, 12, and 13 with a total of 960 cells, correspond to this refinery.

Circuits 10 and 11, with 160 cells, are for the production of the initial plates, and circuits 12 and 13, with 800 electrolytic cells are for the commercial production of electrorefined cathodes.

Technological Advances and Modernization—Permanent work to maintain the quality and competitiveness of the

cathodes from the Chuquicamata refinery includes the following innovations: conditioning of the electrolyte, the liberation plant, protection and covering of cells, replacement of copper starting blanks by titanium starting blanks, and change of the riveting system in the bar-sheet joint by the welding system. The licence has been obtained for the use of initial cathode press, etc.

Technological Advances—The replacement of the copper blanks by titanium blanks was another innovation. For this purpose, in 1975 the Chuquicamata division bought 50 titanium plates. By means of metalographic analysis, the fundamental differences in grain structure in sheets obtained with titanium and copper blanks were assessed. Based on the results obtained, all the copper blanks were replaced by titanium ones (6000). Titanium has an electrical resistivity of 48.2 cm (19 in.), highly superior to that of copper, so that a greater consumption of power should be expected when titanium blanks are used.

Technical innovations introduced by the titanium blanks have led to the replacement of the present method of riveting in the sheet-bar joint (mechanical) by welding, which contributes to a decrease in power consumption and the elimination of corrosion from the effects of electrolyte penetration in the cavities in that zone.

Titanium's high resistance to corrosion permits operation with better temperatures (60°C) and concentrations of 185 g/L (10,807 gr/gal) acid, conditions that improve electrolytic conductivity, thereby lowering energy consumption.

Fig. 7. Concentration smelter flow diagram.

The deposits obtained with titanium blanks are finer grained and free of protuberances. Since the useful life of titanium plates is far superior to that of copper plates, their acquisition has been highly advantageous.

Extraction: Under this heading the following functions related to hydrometallurgical treatment of ore and other copper oxides are grouped:

1. The recovery of copper from oxide ores, at the present time mainly from ore brought from Mina Sur, by leaching with sulfuric acid, to obtain a concentrated solution of copper sulfate.

2. The purification of the copper sulfate solutions, to eliminate impurities that affect the electrowinning of copper.

3. To supply solutions of the correct chemical quality and copper concentration to the electrowinning circuits in the refinery.

4. To produce the sulfuric acid necessary for carrying out the production and research programs, and at the same time, supply the needs of the other production units.

5. To carry out metallurgical research to determine future exploitation of copper oxide resources, as well as the hydrometallurgical treatment of low-grade mineral sulfides. This research is oriented toward the use of the greater amounts of sulfuric acid that will be generated when the new gas recovery projects in the concentrate smelter are implemented.

DESCRIPTION OF THE PROCESS

The extraction of copper from oxidized ores in Chuquicamata and *Mina Sur* is performed by a hydrometallurgical process, in which the ore that has been previously reduced in size is leached by sulfuric acid solutions.

The ore extracted from *Mina Sur* is crushed to a nominal size of 0.18 m (–7 in.) in an Allis-Chalmers 1.37 m (54 in.) crusher, and transported to a 60 kt (66,139 st) bin. The ore then feeds secondary and tertiary crushing in an open circuit. There are two crushing sections, each one composed of a standard 2.13 m (7 ft) cone crusher and two 2.13 m (7 ft) short head cones. The final product fluctuates between 20% and 40% + 9.5 m (3/8 in.).

Water is added to the crushed ore until it reaches a moisture content of 5% to 7%, and then concentrated sulfuric acid is added; 15 to 24 kg/t (30 to 48 lb/st) of ore is used.

The agglomerated ore is sent to leaching vats [14 12 500 t (13,779 st) capacity each] where the ore is treated with solutions of different acid and copper contents, for predetermined periods of time, that solubilize and transform the various types of copper oxide into copper sulfates. The solutions are replaced by solutions of decreasing copper content.

The leaching cycle consists of three essential stages: in the first, the extraction of primary solutions that alter purification (dechlorination-reduction-decanting), are sent to electrowinning; the second is the regeneration of secondary solutions, required for the processing of new batches, and a third stage of eight washings in decreasing copper and acid concentrations, the last being in water. The leached tailings (ripios) are extracted from the vats by means of four dredge bridges, two 6 ft (6.6 st) Mead Morrison and two 12 t (13 st) Wellman-Seaver-Morgan, and transported to dumps in 85 t (94 st) Lectra-Haul trucks.

OPERATING COSTS

Using 1981 as a base, operating costs are distributed as follows:

Wages	32%
Materials and fuel	42%
Services	7%
Transport to port	2%
Other income and expenditure	17%

PRODUCTION AND FUTURE TECHNOLOGY

Production

Since 1971, the Chuquicamata complex has been managed and operated by Chilean professionals and personnel. The following production figures show the performance from 1967 to 1981.

Year	Tons fine Cu (thousands)	Year	Tons fine Cu (thousands)
1967	277	1975	305
1968	279	1976	446
1969	283	1977	478
1970	265	1978	501
1971	285	1979	507
1972	265	1980	511
1973	297	1981	472
1974	389		

Future Technology

As the decreasing ore grade causes a decline in production, a metallurgical research program has been undertaken to determine the possibilities of the eventual application of the following technologies: flash smelting, heap leaching, leaching in waste dumps, low-grade ore and gravel, solvent extraction, autogenous or semiautogenous grinding mill, in situ leaching, and slag flotation.

9.7 Shirley Basin Mine

M. I. RITCHIE

INTRODUCTION

The mines and mills of Pathfinder Mines Corporation have been actively producing uranium concentrates in Wyoming since early 1958 when the Lucky Mc facilities in the Gas Hills district, Fremont County, first achieved operating status. The company acquired claims in the Shirley Basin district, Carbon County, Wyoming, and shortly thereafter, in 1960, produced uranium ore from these holdings by underground mining methods. During the underground mine life from 1960 to 1963, approximately 99.8 kt (110,000 st) of ore was mined containing 544 311 kg (1.2 million lb) U_3O_8 . The ore was transported to the Lucky Mc mill for processing to yellowcake. After gaining valuable experience regarding geologic and hydrologic conditions and studying various alternatives, patented solution mining techniques were introduced and successfully implemented from 1963 to 1970. Concentrate extracted from solution mining was some 680 388 kg (1.5 million lb) of U_3O_8 . In November of 1968, the company announced that it would develop the uranium reserves by open-pit mining methods and would construct a processing facility capable of producing 1 133 981 kg (2.5 million lb) of U_3O_8 per year. For the period from 1968 to 1982, approximately 5.7 Mt (6.3 million st) of ore containing 9 525 440 kg (21 million lb) of U_3O_8 has been mined by surface mining methods. The location of the area is shown in Fig. 1.

In December, 1976, Pathfinder Mines Corporation (known as Lucky Mc Uranium Corporation) was incorporated as a wholly owned subsidiary of Utah International Inc. in connection with the merger of Utah International Inc. and the General Electric Co.

In March 1982, 80% of the capital stock of Pathfinder was acquired by COGEMA Inc., a United States subsidiary of Compagnie Generale Des Matieres Nucleaires (COGEMA), a French corporation. COGEMA, wholly owned by the French Atomic Energy Commission, is involved in uranium operations around the world.

CLAIM ACQUISITION AND EARLY EXPLORATION

After the initial exploration and development phases of the Lucky Mc mine were completed and the project was turned over to the mine management staff in the spring of 1955, the company's exploration group was charged with finding additional uranium reserves that could contribute ore for the new mill under construction. Initially, the area of study was within an 80-km (50-mile) radius of the Gas Hills district. Background studies and preliminary geologic criteria developed from other Tertiary basins in Wyoming yielded evidence that considerable potential existed for major uranium deposits in the Shirley Basin area. In response to this information, an exploration effort was set into motion and the restrictive 80-km (50-mile) radius around the Lucky Mc mill was extended to a 161-km (100-mile) radius.

By July 25, 1957, the activity in progress included compilation of land status, and maps were obtained from the Bureau of Land Management in Cheyenne, WY, by the Land Department. Preliminary geologic and field reconnaissance of Shirley Basin was assigned. The field camp was being

assembled by closing the facilities at Copper Mountain northeast of Shoshoni, WY, and from surplus equipment in the Gas Hills.

On July 27, a convoy of 17 vehicles including one drill rig and trucks loaded with 102 × 102-mm (4 × 4-in.) claim stakes and assorted camping equipment left the Gas Hills and arrived in Shirley Basin.

The first priority was to stake claims of projected potential and to cut off the northward advance of competitor survey crews. The projected potential area was determined from surface geology maps, land status maps, and the known locations of surface mineralization. The recently acquired experience in the Gas Hills exploration program was most beneficial in this analysis. In the targeted area, the surface was covered with thin remnants of the White River formation. The subsurface Wind River formation was composed of arkosic sandstones and shales that had been deposited on an erosional surface of deformed Cretaceous sediments.

On July 28 the first claims were located and by July 30 over 250 claims were staked and filed in the Carbon County Recorder's office. On Aug. 17, 1957, it was reported that three of the first 11 drill holes had intersected significant mineralization, with the best intercept of 0.3 m (1 ft) of 0.80% e U_3O_8 , in a zone 76 to 91 m (250 to 300 ft) deep in the eastern portion of the claim block. This area later was designated area 1. Progress during the summer and early fall was summarized in a Sept. 13 report:

To date, approximately 412 claims have been staked and validated. . . . In addition, 1080-acre state leases have been obtained in the area of greatest interest and negotiations have commenced for other favorable ground. A campsite has been located, water well drilled, and summer camp installed. The winterized camp from the Gas Hills will be moved to this site next week. Forty-four deep holes have been completed, twenty-four on a widespread net for geology, and twenty discovery holes have intersected high-grade mineralization. An estimated 150,000 st at 0.75% e U_3O_8 of potential ore is indicated by the drilling to date. . . . The geologic potential probably is greater than 300,000 st.

By December 1958, drilling had expanded the reserve to an estimated 1 496 855 kg (3.3 million lb) of U_3O_8 at an average grade of 0.69%. On Oct. 28, 1957, the US Atomic Energy Commission (AEC) had announced that future domestic allocation would be limited to ore reserves developed by the announcement date. This production limit was later modified by an announcement on Nov. 24, 1958, that provided for some expansion of production in Wyoming. The Shirley Basin annual allocation of 116 120 kg (256,000 lb) through 1962 was increased to 158 757 kg (350,000 lb) to the end of the contract period in 1966. With the identification of ample reserves to fill the allocation allowed by the AEC, Shirley Basin moved from an exploration program to mine development.

UNDERGROUND MINE DEVELOPMENT

The corporate decision to proceed with underground mine development and to plan deliveries of mined high-grade ore to the Lucky Mc mill for processing became a reality when construction commenced in the spring of 1959.

Fig. 1. Location of the Shirley Basin mine, Carbon County, Wyoming.

Surface Plant

The surface plant consisted of two main steel-frame, corrugated iron buildings. A 7.6×30.5 -m (25×100 -ft) building housed the 187 kW (250 hp) double drum hoist, two $0.850\text{-m}^3/\text{s}$ (1800-cfm) compressors, and a standby power-plant consisting of three 300-kW diesel generators. The second building, connected to the headframe house, contained mine offices, warehouse, shop, change room, radiometric assay laboratory, and first aid room. Timber storage and framing facilities were included in the mine yard.

A mine townsite constructed near the shaft site included 84 trailer spaces, a bunkhouse, mess hall, community building, and school facilities for grades one through eight.

Mine Development

The mine access was through a 3.7-m (12-ft) diam, circular, concrete-lined, four-compartment vertical shaft 111 m (365 ft) deep. Men, supplies, ore, and waste were hoisted through two compartments in combination cage-skip car dumpers. The third compartment contained a manway and electric cables. The service compartment contained a 762-mm (30-in.) ventilation duct, a 152-mm (6-in.) pump column, a 152-mm (6-in.) compressed air line, and a 51-mm (2-in.) potable water line. The shaft was sunk in 1959 by the construction division of the company.

In general, development was by haulage drifts on the

2070-m (6790-ft) level at a depth of 99 m (324 ft), driven south and southwesterly along the trends of the 2067-m (6780-ft) and 2079-m (6820-ft) roll front systems. Drifting through the unconsolidated, saturated sediments required back and side spiling with excavation by pneumatic spaders. Drift support was achieved with timber sets that included bridge caps.

Haulage drifts had 762-mm (30-in.) gage track, 152-mm (6-in.) or 102-mm (4-in.) compressed air line, 25-mm (1-in.) drill-water line, power cables, 152-mm (6-in.) pump-discharge line, and vent tubing when needed. Track grade was maintained at 0.5%. Haulage in the track drifts was done with 1.8-t (2-st) ridge box cars. Trains were pulled with two 2.7-t (3-st) and two 0.9-t (1-st) storage-battery locomotives on the 2070-m (6790-ft) level. The 2079-m (6820-ft) level ore zones were developed through two-compartment timbered raises, driven from the haulage drifts.

The underhand stopes in the 2067-m (6780-ft) ore horizon were developed by square set *scrams* driven on a decline from the haulage drifts to the bottom of the ore and advanced through the ore to a grade times thickness cutoff of 1.20 with a minimum thickness of 1.2 m (4 ft).

Mining Methods

Mining the unconsolidated ore bodies required overhead spiling, square set support, and excavation with pneumatic

spaders. The broken ore was removed with slushers, feeding into mine cars or chutes. Stopping advanced along the roll fronts and retreated towards the haulage drift or development raise.

Sand filling of completed stopes along the haulage drift achieved stabilization of the drift pillars. Drift maintenance and ground support repairs were a major program in those areas where the stopes had caved to the drift pillar line. The repair program involved up to 20% of the underground crew working on a nonproduction shift. Replacing the drift caps with 45.4 kg-(100-lb) *H* beams provided only temporary support. The installation of yieldable steel arches through this drift section provided stable ground support. Table 1 provides summary data on mining quantities for the years the underground mine was operated.

Ventilation

During the shaft sinking phase and early stages of development, ventilation was provided by a 18.7-kW (25-hp) fan that forced air through a 762-mm (30-in.) casing installed in the service compartment of the shaft. Later, connections were made to the two 762-mm (30-in.) boreholes drilled from the surface. Each borehole was equipped with a 29.8-kW (40-hp) fan, a 2.1-MJ (2-million-Btu) propane-fired heater, and emergency escape facilities. The 29.8-kW (40-hp) fans delivered 11.3 m³/s (24,000 cfm) of heated, downcast air into the haulage level. Two additional 305-mm (12-in.) boreholes, equipped with 18.7-kW (25-hp) fans, increased the total volume of air upcast through the shaft to 26.9 m³/s (57,000 cfm). Auxiliary ventilation to the working faces was provided with 11.2-kW (15-hp) fans through vent tubing.

Mine Drainage

The Wind River formation, composed of unconsolidated and uncemented sand, gravel, and clay, was an artesian aquifer completely saturated with water to within 30.5 m (100 ft) of the surface. A mine-dewatering well field, consisting of eight 305-mm (12-in.), gravel-packed wells was completed before shaft sinking commenced. At the time the station was cut, the water table had been lowered from the 30.5 m (100

ft) depth to an average depth of 104.2 m (342 ft). The pumping rate during this period was 0.28 m³/s (4500 gpm). Eleven additional wells were installed as mine workings extended beyond the well field drawdown area. An average pumping rate of 0.32 m³/s (5000 gpm) was required to hold the water table at a depth of 111 m (365 ft).

The pump station was constructed on the 2070-m (6790-ft) level at a depth of 98.8 m (324 ft) and two 37.3-kW (50-hp) pumps discharged 0.03 m³/s (500 gpm). The settling sump ahead of the pumping sump was cleaned periodically with a sludge pump discharging into mine cars. Standby emergency pump capacity was achieved by the installation of two 56.0-kW (75-hp) submersible pumps in the shaft. The underhand stopes required continuous pumping, with submersible pumps discharging into a 152-mm (6-in.) line in the haulage drift.

Although longhole drilling for dewatering was employed to provide drainage ahead of and over the haulage drifts, on several occasions erosion through the longholes induced caving ahead of and back over the drift section. Another method of dewatering ahead of drifting was to discontinue the full-face advance and drive a square *scram* ahead of the drift. Drifting would be suspended until the area was drained.

Sampling and Grade Control

Ore control procedures consisted of channel sampling of drift and stope walls, muckpile grab, and sampling of muck in mine cars. Grade was determined with a beta-gamma scaler. Mined ore was stockpiled in four ore blending piles with a grade ranging from 0.30% to +0.90% U₃O₈. Division between piles was at increments of 0.20% U₃O₈. The submarginal ore blending pile included ores with a grade range of 0.10% to 0.29% U₃O₈.

In January 1963 the decision was made to phase out the conventional underground mine operation. The factors contributing to this decision were the poor mining conditions and the costly ground support required, revision of the AEC program allowing ore substitution without loss of allocation, and the promising results being obtained from solution min-

ing tests. After all salvageable material was removed, the mine was allowed to flood in July 1964.

SOLUTION MINING

Following consultation with reservoir engineers, a pilot program was initiated in the spring of 1961 to test the feasibility of in-place leaching of uranium, or solution mining. Dewatering the mineralized zone was not surmised to be necessary as the natural ground water would act as a containment shell for the leaching solutions. Thus, an area was selected for the initial experiment as far away from the shaft and underground operation as property boundary and proven mineral reserve would allow. See Fig. 2 for the location of the various mining phases. The patented well design and development, pattern size and shape, leaching chemistry, and uranium recovery from production well solution has been adequately documented (Ritchie and Gardner, 1967; Ritchie and Anderson, 1968) and following the pilot program, 680 386 kg (1.5 million lb) U_3O_8 were produced on a commercial basis to 1970. All material produced was finished to converter specifications at the Lucky Mc mill.

FEASIBILITY OF OPEN PIT DEVELOPMENT

The first serious feasibility study to examine the economics of open-pit mining was submitted to management in August 1967. At the time, proven, indicated, and inferred reserves totaled 5.9 Mt (6.5 million st), 0.22% grade, con-

taining 12 927 383 kg (28.5 million lb) U_3O_8 . Forty-two percent of this reserve total was selected, based on the most favorable strip ratio, for design into the preliminary pit study. The volume of ore, coupled with its relatively low grade, eliminated consideration of hauling to the Lucky Mc mill. Thus, an onsite concentrator was part of the economic feasibility study.

Following the favorable economic indications contained in the first study, a development drilling program of 76 200 m (250,000 ft) was authorized. The results expanded the proven reserve in area 2, the claim group previously exploited by underground mining and still producing from solution mining, to 8 255 381 kg (18.2 million lb) U_3O_8 . The development drilling program successfully increased the total reserve by 14.4%, but more significantly, increased the proven category of reserves by 55.9%.

Six contiguous pit phases were engineered, requiring an estimated 65.8 Mm³ (86 million cu yd) of overburden removal for the extraction of 4 082 331 kg (9 million lb) U_3O_8 . The economies of this pit development and an appropriately sized mill formed the basis for a final feasibility study.

OPEN PIT DEVELOPMENT

On Nov. 1, 1968, the announcement was made by the company that the Shirley Basin mine would be converted to a large scale open-pit operation, and that a new 1089-t/d

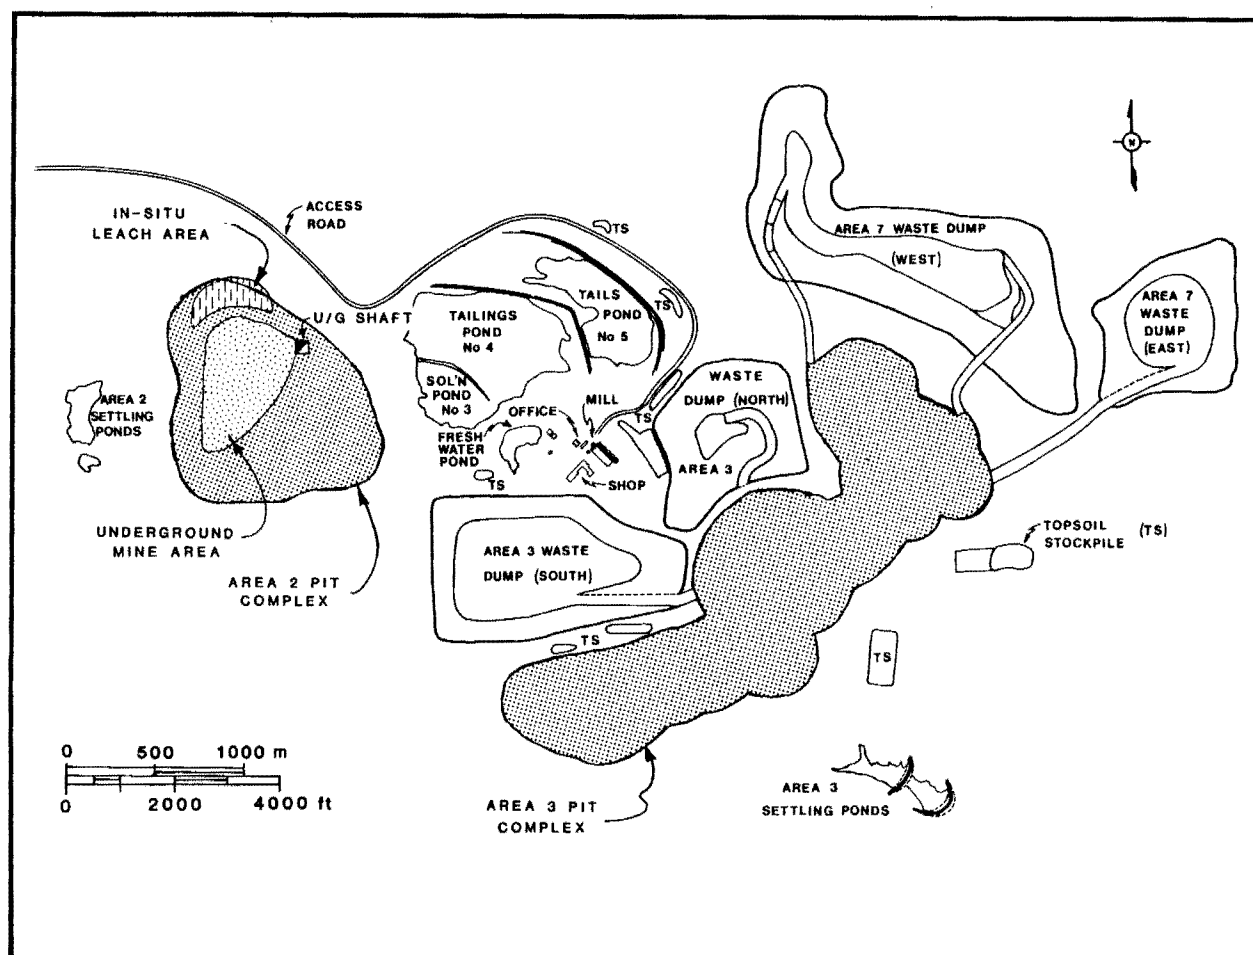

Fig. 2. Mine map, Shirley Basin mine.

(1200-stpd) mill would be constructed to accommodate the resulting ore production.

In the following year, a new warehouse and equipment maintenance facility were constructed, a new tailings basin and dam were completed, and an engineer-contractor was engaged to begin construction of the new mill. In addition, the first of the large-scale stripping equipment was delivered to begin the excavating of the initial pit.

The equipment purchased, after a study of various stripping options, was large-scale, three-axle scrapers, 24.5-m³ (32-cu-yd), 72.6 t (80-ton) capacity scrapers, and dual crawler tractors for push loading. Mid-sized, self-loading scrapers were acquired to load and haul the waste material between ore pockets in the ore zones, and hydraulic backhoes and 22.7-t (25-ton) trucks were used for the actual ore mining.

The method of excavating waste from around ore pods within the ore body and then mining the ore areas with backhoes had been pioneered and proven at the Lucky Mc mine. This method consisted of defining ore pods by the use of portable Geiger counters, very carefully excavating the adjacent waste, and then mining with a relatively small mining unit in order to minimize dilution and yet insure total excavation of any available ore. By the end of 1969, the bulk of the stripping equipment had been delivered and slightly over 7 Mm³ (9 million cu yd) had been removed from the initial pit.

Ground Control

In March 1970, the pit experienced the first of many major slope failures that were to plague the early years of this project. The original pit designs had been made using slopes of around 45°, but after suffering numerous failures even before reaching ore depth approximately 122 m (400 ft below surface), it became apparent that nothing steeper than 33° would remain in place long enough to complete ore extraction.

Another problem noted during this phase of operation was the poor performance of the scrapers selected for stripping. As the pit became deeper, water was encountered and a pumping system was installed to move this water to the surface for disposal. The area of active removal, however, became very wet at times and this, combined with high clay content material, made the loading of the three-axle scrapers very difficult. Near the end of 1970, a study was instituted to reevaluate the stripping methods being used and recommend alternatives. As a result of this study, it was decided to move the bulk of the waste material with a standard truck-shovel combination.

To proceed as soon as possible with this recommendation, the truck-shovel units were ordered and began arriving in mid-1971. By the end of that year, the bulk of waste material was being moved by the new truck-shovel combination, 2 11.5-m³ (15-cu-yd) electric shovels and 12 108.9-t (120-ton) trucks. With just a few startup and operator training problems the new stripping method won rapid acceptance and proved much more economical than the scraper method.

It was recognized that even though the shovels were the preferred method of overburden removal, they could not handle the task singlehandedly. Because of the sometimes rapidly changing conditions due to slope failures, some scrapers were necessary to cope with unexpected problems. Scrapers also were necessary to do the final stripping just above ore so that no ore would be inadvertently removed as overburden.

Pit wall slope failures continued through 1971 and this period saw many man-hours devoted to solving this problem.

Near the end of the year, a monitor net had been installed around the pit perimeter, a leading geotechnical engineering firm had been retained to do a slope stability analysis, and some experimental drilling designs to drain the slopes had begun.

All of these actions eventually proved fruitful. The monitoring net, while not preventive in nature, at least provided early warning about impending failures and provided data for future designs.

The geotechnical engineering firm provided a report in 1972 that analyzed the strength characteristics of the soils around the pit areas and gave various safety factors for different slopes configurations. A compound slope configuration was eventually utilized; this was essentially a 33° slope on the top section and 27° on the bottom section. This was not a fail-proof slope, but did provide some measure of stability and decreased the magnitude of the slope failures.

Pit Dewatering

Various combinations of drilled holes were tried to accomplish the draining of pit walls. The most practical of these was a combination of vertical drains and horizontal drains. This method consisted of a series of vertical holes drilled from the surface near the pit perimeter. These holes were completed as wells with a slotted PVC pipe and gravel-packed for the entire length of the hole. At the same time, holes slightly elevated from the horizontal were drilled from the pit bottom in the general direction of the vertical drains. This combination of holes allowed any perched water or elevated water table to drain down the vertical holes and out the near-horizontal holes into the pit. From here, the water was collected in the normal pit dewatering sump and pumped to the surface. Another dewatering technique, useful in some areas, was to drill and complete a well into a zone known to provide water to a slope. This well would be pumped at a rate high enough to create a drawdown which resulted in drying of the slope. These methods of dewatering slopes aided stability considerably and still are being used today.

Mine Production

Slides continued to be a problem through the early years until 1974 when the first pit was excavated and mined without any slides of major proportions. Instability still continues to be a problem, but is dealt with by using techniques learned in the earlier years.

Stripping and mining quantities generally continued to increase from the beginning in 1969 through 1976. Table 2 shows stripping and mining quantities for the period 1969 through 1986. Also, during this period, three-axle scrapers were replaced with large two-axle, push-pull scrapers. These units were difficult to maintain but were far superior in the sometimes difficult stripping situations encountered.

During this period all stripping and mining were being carried out in one general location (area 2). Each new *pit* was actually an extension of the previous excavation and resulted in one large pit. As pit extensions were mined out, they provided areas for dumping the waste material from the pit then being excavated. This practice was perfected to the point where almost no material was being hauled to the surface but rather "backfilled" into previously mined-out pits.

During 1976 and early 1977, a large-scale study of a new mining area was intensified. This new area (area 3) had long been known to contain good mineralization and the mill was actually positioned in a location to take advantage of this new area should it ever be mined (the mill location being

about midway between the original mining area and the new one).

Pit designs were drafted and studied and a complete analysis of stripping methods was done for this new area. The analysis indicated that a truck-shovel combination would be the most economical method of stripping. In mid-1977, a new truck-shovel fleet, one 20.6-m³ (27-cu-yd) electric shovel and six 154.2-t (170-ton) trucks, was purchased and began stripping in this new area. The new area produced its first ore in September of 1979.

This period showed, again, a generally slow but steady increase in the volume of material stripped and tons of ore mined. This trend continued until September 1980 when the first of several cutbacks was deemed necessary. These cutbacks in production were, indirectly, adjustments to the decrease in uranium prices which had begun their decline in 1979.

The operation, at present (1983), continues to be mainly a truck-shovel stripping operation with aid from a scraper fleet. All mining activity in the original pit area (area 2) has been completed, and all stripping and mining activity is now carried on in the area started in 1977 (area 3). Large areas of the original pits, pit slopes, and dumps have been regraded and reclaimed in accordance with the state-issued mining permit.

The manpower growth kept pace with the operation, starting out with 128 employees in 1969 and peaking in mid-1980 at 620 employees. Presently, at the reduced rates of production, employment has decreased to 135 employees.

MILL CIRCUIT DEVELOPMENT AND PERFORMANCE

Contrary to traditional uranium mill design at the time, several unique features were introduced into the engineering of the Shirley Basin mill, setting a precedent that has since been emulated by many uranium processors. Fig. 3 presents the flow diagram for the mill process. The Shirley Basin design eliminated all crushing and conveying steps. Run-of-mine ore is introduced into the 1633-t/d (1800-stpd) mill

from an exterior blending pile pad by a front-end loader through an inclined bar grizzly to the loading hopper. The material is fed at a rate of approximately 181.4 t/h (200 stph) on a pan feeder into a 5.5-m (18-ft) diam by 1.8-m (6-ft) long semiautogenous grinding mill; little grinding media is required in this mill. The material is ground, discharged from the mill, and pumped to a bank of six DSM-type (Dutch State Mines) screens. The sized product, all $-850 \mu\text{m}$ (-20 mesh), is then pumped to pulp storage tanks and the oversize is recirculated back to the mill for regrind. Operating this circuit for 8 to 9 hr per day produces sufficient feed for the 24-hr continuous leaching operations. The pulp, at 60% solids, is stored in two 7.6-m (25-ft) diam by 15.2-m (50-ft) high, flat-bottomed, 345-kPa (50-psi) air-agitation tanks; no problems have been encountered with keeping coarse-grained particles in suspension once the inverse cone deadbed was formed. The pulp is metered from the storage tanks to leaching on a continuous basis. The leaching vessels consist of four conical-bottom, rubber-lined, air-agitation Pachuca tanks 6.9-m (22.5-ft) in diam by 14.2-m (46.5-ft) high. Fresh feed to leach is sampled and monitored in a mass flow station. Sulfuric acid and sodium chlorate are also added at this juncture; steam is also added in winter. The retention time in leach is approximately 18 hr and is sufficient to extract up to 98% of the uranium into solution. Leach discharge is classified in a hydrocyclone into two size fractions, coarse and fine. Each fraction is treated separately; the coarse material has the uranium in solution washed from it in a series of six countercurrent sand-washing hydrocyclones and the fine-sized fraction is washed through a series of six 30.5-m (100-ft) diam countercurrent decantation thickeners. Pulp streams in both circuits are washed by recycle solution and after optimum recovery, the uranium-depleted, coarse-sand underflow from the last cyclone and the thickened fines underflow from the last thickener are combined and pumped to the tailings ponds where all pulp and associated liquor are retained.

The pregnant solution overflowing the No. 1 thickener is pumped through a clarifying bed of granular activated

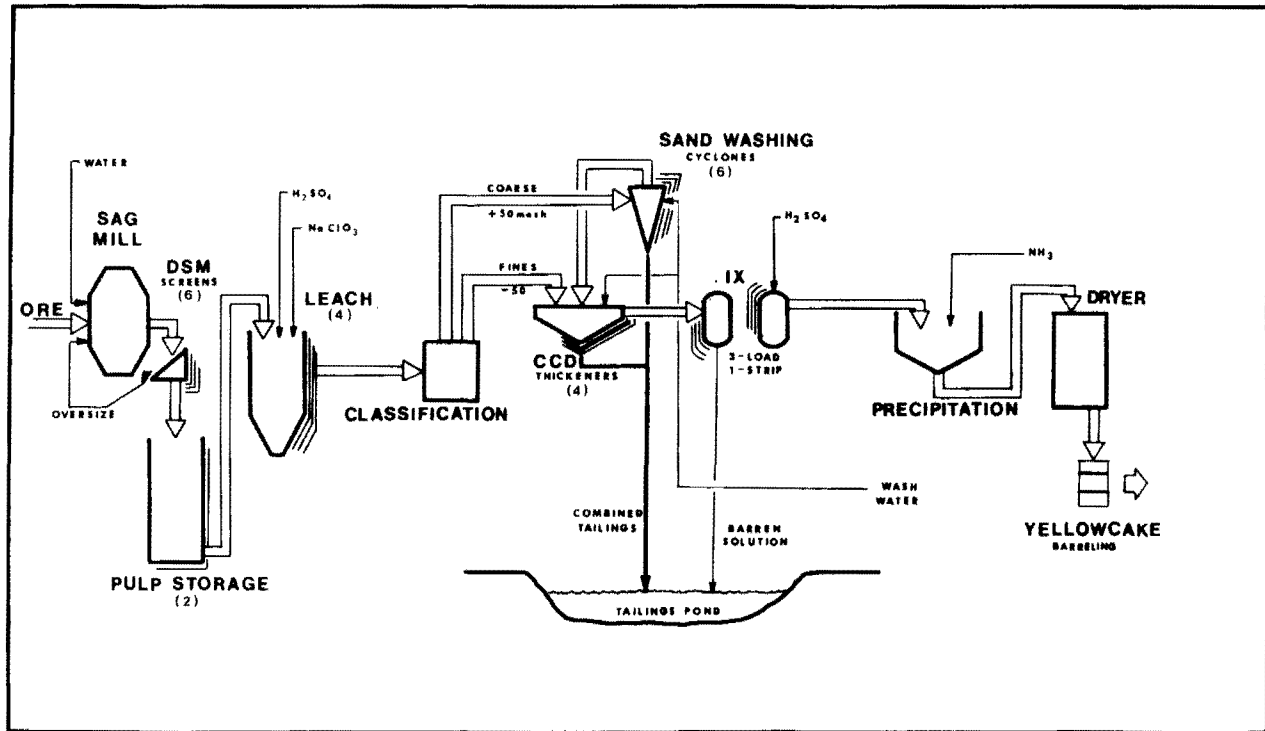

Fig. 3. Shirley Basin flow diagram for the mill process.

carbon and any extraneous slimes are removed. The completely clear liquor containing the extracted uranium is then fed to a set of fixed-bed ion exchange columns. The columns each contain a 8.5-m³ (300-cu-ft) bed of a weak-base tertiary amine resin. Each set of columns consists of four beds and in general, only three are employed for uranium absorption while the fourth is being eluted. The strip liquor, or eluate, has a chemical composition of 2 M sodium chloride and 1 M ammonium sulfate. Approximately 6½ bed volumes of strip liquor are sufficient to strip all of the uranium from the resin bed. Due to the exchange characteristics of the resin, the first 1½ bed volumes of liquor are high in uranium, high in sulfate, low in chloride, and have a high sodium ion concentration. This portion of the liquor is designated as the No. 1 concentrated eluate and is guided to a separate tank. The ensuing 2½ bed volumes, also high in uranium, contain high values of chloride. This liquor is designated as the No. 2 concentrated eluate and it too goes into a separate circuit tank. The final 2½ bed volumes are designated as recycle and are stored separately.

Because the stripping solution is neutral, the acidity of the Nos. 1 and 2 concentrated eluates is very low, and these solutions are pumped separately to respective precipitation tanks where the uranium product is precipitated by neutralization with ammonia gas. The precipitated products in each case flow to separate yellowcake thickening vessels where, in the case of the No. 1 circuit, the overflow material is polished and, being low in chloride, is discarded to tailings. The material overflowing the second yellowcake thickener is guided to eluate makeup tanks where the chloride concentration is replenished with fresh saturated brine before being recirculated to fresh eluate storage.

The settled uranium precipitate in the Nos. 1 and 2 circuits is combined after initial thickening. The solids so pro-

duced are fed to a third yellowcake thickener designated as the washing thickener. The overflow from this vessel is polished and discarded to waste as it contains no salvageable chemical constituents. The thickened solids are then dewatered in a drum filter prior to introduction to a multi-hearth, roaster-type dryer. The completely dried solids, discharging from the dryer, accumulate in an enclosed hopper and, on a batch basis, are automatically packaged in 0.21-m³ (55-gal) drums after being sized through a small pulverizer.

Some of the differences between traditional flowsheets of the period and the Shirley Basin facility are in the ore handling section where, with no conveyors or crushing, direct conversion of the run-of-mine ore to a pulp is achieved. Significant capital cost savings and a substantial reduction in operating costs were achieved. This direct conversion also eliminates the requirement for costly dust-control equipment normally associated with conveyors and crushing plants.

The decision to employ a semiautogenous mill and establishment of the dimensions resulted from pilot-plant test work conducted on several hundred tonnes of typical material run through a mill, 1.8 m (6 ft) diam by 0.61 m (2 ft) long, installed at one of the company's other mines.

DSM-type screens were favored, as opposed to cyclone classification, due to successful utilization of these units at the Lucky Mc mill and the fact that a closer control of grain size can be achieved, facilitating storage of the pulp in air-agitation vessels without segregation.

It is particularly interesting to analyze the power requirements in the ore handling section, comparing one flow scheme with the other. In Lucky Mc mill's old circuit, the single shift operation of crushing, conveying, partial drying, dust collection, and sampling required 3432 kWh (4600 hp-hr). Added to that, there is the conveying (from ore bins to mill), grinding, and pump feeding to leach on a 24-hr basis

of 4386 kWh (5880 hp-hr) to total 7818 kWh (10,480 hp-hr). The Shirley Basin circuit requires a single-shift operation of a feeder, 522-kW (700-hp) mill, and three slurry pumps consuming 4580 kWh (6140 hp-hr), plus a 24-hr requirement of a compressor for pulp air agitation and a leach feed pump, adding 3312 kWh (4440 hp-hr), to total 7892 kWh (10,580 hp-hr). It can therefore be concluded that the energy charges are approximately equal in either case (with perhaps a higher demand charge at Shirley Basin), but the operating costs in the semiautogenous mill flowsheet are less than half those of the old Lucky Mc circuit due to significant savings in labor and maintenance supplies.

The use of conical-bottom Pachuca tanks is not new. They are the standard configuration of leaching vessels in South African and Canadian uranium plants. However, in the United States, due to the general coarse grading of material to be leached, mechanical agitators are almost exclusively used. Again, pilot plant work by the company showed that even though the grind was nominally a $-850\text{ }\mu\text{m}$ (-20 mesh) grading, Pachuca tanks without excessive air agitation could quite easily handle a 50 to 55% solids acid pulp without segregation. There have been arguments over the years concerning the relative merits of air vs. mechanical agitation in leach vessels. Again a comparison can be made between the two installations. At the Lucky Mc mill, processing a comparable tonnage, the installed horsepower is 172 kW (230 hp) on the agitators. The retention time averages 14 hr, or stated another way, 12.2 kW/h (16.4 hp per hr) of residence time. The Shirley Basin mill requires the maximum service of one 149-kW (200-hp) compressor, but the retention time is 18 hr, or 8.28 kW/h (11.1 hp per hr) of residence time. Although this comparison is not absolutely conclusive, the absence in a Pachuca of any moving parts in the acid and abrasive environment contributes to lower maintenance costs.

The sand-washing hydrocyclone circuit was introduced approximately four years after the initial commissioning of the plant. This circuit enabled plant throughput to be increased from 1089 t/d (1200 stpd) to the presently licensed 1633 t/d (1800 stpd). The circuit has functioned very well,

and because of its uniquely designed sump box system, flexibility of maintenance and repair to an individual cyclone or pump can be effected without shutdown of the circuit. This specific design has been emulated in at least two other uranium mills. Table 3 presents a summary of the yearly mill production from 1969 through 1986.

The thickener circuit is not unique in any of its design features. Density of the last thickener underflow is controlled using a variable speed pump.

The clarification section has some novel features. The circuit consists of two cone-bottomed tanks with a filtering grid constructed inside the cone. The tanks contain a centrally located cylindrical well, supported from the top and sides, and just protruding into the cone section. In operation, the tank is approximately half filled with a -1.40 mm (-14 mesh) + $600\text{ }\mu\text{m}$ ($+30$ mesh) activated carbon. The unclarified solution is distributed over a splash plate and onto the surface of the carbon. The clarified liquor is pulled through the carbon bed and out through the retaining filter system. One unit is in operation while the other is being backwashed or is on standby. When the carbon bed is fouled and requires backwashing, the pregnant solution flow is stopped and water is introduced through the filtering section to expand the bed. At the same time, air and water are introduced at the apex of the cone, causing carbon to flow up through the well and circulate. A peripheral launder evacuates the slimes and backwash water away from the unit and returns them to the No. 1 thickener. This peculiar action of backwashing not only effectively cleans the bed, but prevents gypsum from forming large conglomerate pieces with the carbon.

The Shirley Basin mill was the first commercial plant to use a weak-base resin. It was selected because it has capital cost advantages over an eluex system and a straight solvent extraction system for this volume of solution and also because it results in a more economical operation than either of the two aforementioned processes and will produce a premium grade of product. The weak-base resin does not exhibit as high a loading for uranium as does a strong base anionic

resin. However, it is more selective and due to the ease with which it elutes with a neutral and inexpensive reagent, this lower capacity can be tolerated. The predominance of ammonium sulfate in the liquor fed to precipitation results in a product precipitate that is very low in sodium ion.

The reason for the dual or separated precipitation circuits is to effect a bleed of sodium ion from the circuit and at the same time conserve, by recycle, the chloride ion necessary for uranium stripping. The subsequent flowsheet in the product recovery circuit is designed around maximum washing of the precipitated product in order to reduce the halogen content in the final product.

The use of roaster-type dryers is not new; the application has been widely used in the uranium industry. The entire drying and packaging circuit is completely enclosed, with vapors and sublimed salts being vented through a scrubber prior to discharge to the atmosphere. All precautionary measures have been incorporated to avoid the exposure of employees to radioactive-bearing particles.

Except for the six 30.5-m (100-ft) thickener vessels, all other pieces of equipment are compact enough to be contained within one building structure, 131 m (430 ft) long and 57.9 m (190 ft) wide. Fig. 4 presents a site plan of the mine's surface facilities, including the mill building and some of its major circuits. This compactness of design facilitates control from a central instrumentation panel located in the heart of the mill building. Instrumentation in the mill follows the basic principle that instruments are most effective when they

accurately record process variables but do not control corrections. In almost all instances, correction must be made manually.

The control panel is divided into three segments:

1) At the top of the panel is a semi-graphic representation of the entire process, complete with machinery running lights.

2) All of the recording and indicating instruments are located in the center portion. Included in this package are 3 density-recording gages, 14 magnetic flowmeter readouts, oxidation-reduction potential and conductivity recorder showing the oxidizing level and acid concentration in the leach circuit, and numerous tank level indicators.

3) On the console portion of the panel, a full ion exchange graphic is depicted, including column pressures and valve operating switches. The entire ion exchange section is manually, but remotely, operated from this central point. The circuit design is sized so that only one cell in either exchange set can be stripped of its uranium at a time. This necessitates careful scheduling of the loading cycles, but at the same time, lessens the chances of error during elution. The circuit has a theoretical surge capacity of 6350.3 kg (14,000 lb) of U_3O_8 per 24-hr period, or double the nameplate capacity of the mill. This was a deliberate design consideration due to the expected fluctuations in the grade of ore from the open-pit operation.

Chemical and analytical control of the circuit is largely dependent upon an X-ray emission spectrograph installed in

the laboratory, located below the central control room. Experience has shown that uranium values can be consistently distinguished in parts per million for solution samples, or in thousandths of a percent in solid samples (especially if the emanations pass through a vacuum path) with an equipment configuration that includes a molybdenum target, a lithium fluoride crystal, and a scintillation detector. The laboratory is equipped to handle all incidental determinations required for full plant control, including sodium concentrations using an atomic adsorption spectrophotometer.

The ore feed, in comparison with many producing areas in the world, can be considered a high acid consumer. The average reagent consumption is:

	<u>g/kg (lb per st) of ore</u>
Sulfuric acid	40.0(80.0)
Sodium chlorate	1.0(2.0)
Flocculant aid	0.08(0.15)
Sodium chloride	4.5(9.0)
Anhydrous ammonia	1.0(2.0)
Activated carbon	0.05(0.1)
IX resin	0.05(0.1)

Compact design (essential for the severe winter conditions) along with the process measurement controls call for an anticipated shift crew of one supervisor and three operators. The supervisor is required to perform some analytical test work on process control samples in the central laboratory in addition to direction of the operation. Single shift operations and necessary cleanup require four to six men.

TAILINGS MANAGEMENT

The present tailings impoundment occupies approximately 148 ha (365 acres) in a dry wash that originally drained northeastward toward Spring Creek. The impoundment is contained on three sides by natural landforms and on the fourth side by dams. The impoundment consists of three ponds. Fig. 5 shows a plan view of the tailings impoundment. Mining operations prior to 1970 created a series of mine water settling ponds (ponds 1, 2, and 3). The material in ponds 1 and 2 was excavated and removed during the development of the area 2 pit complex.

Pond 3 presently contains approximately 535 331 m³ (434 acre-ft) of solution, retained by a compacted earthfill dam (dam No. 3). Dam No. 4 was constructed to accommodate tailings generated by the mill, which began production in 1971; dam No. 4 is a compacted earthfill dam with a crest elevation of 2167 m (7110 ft) and an impound volume of approximately 4.9 Mm³ (4000 acre-ft).

Construction of dam No. 5 began in 1975. The dam is an engineered earthfill dam that was subject to continuous engineering inspection during construction. The dam has a crest elevation of 2167 m (7110 ft) with a maximum height of 19.8 m (65 ft) and a length of approximately 1859 m (6100 ft). The impound volume is 4 441 000 m³ (3600 acre-ft). Dam No. 5 consists of three zones: (1) a low permeability upstream embankment constructed of compacted mine overburden; (2) a chimney drain constructed of cycloned tailings underflow; and (3) a downstream cover of compacted mine overburden.

As of December 1986, ponds 4 and 5 contained approximately 6.2 Mt (6.8 million st) of tailings solids. There have been no solid tailings placed in pond 3. The company antic-

ipates that an additional 2.9 Mt (3.2 million st) of tailings solids will be generated before economical ore reserves are exhausted. These additional tailings will be initially deposited in the deep hollows of the impoundment to create reasonably level settled surfaces. Later, hydraulic placement will continue concurrently with a systematic mechanical movement of the beached tailings to shape the preliminary contours prior to the neutralization step. In this way, the amount of final contouring necessary during reclamation will be minimized. Presently, calculations indicate that the drain-dried tailings will settle to an elevation of approximately 2163 m (7096 ft) at the southwest periphery of pond No. 3 and northeast periphery along dam No. 5. The crown elevation of approximately 2167 m (7109 ft) will occur near the center of pond No. 4.

COST HISTORY

The area 2 mine lands were staked and patented by the company during 1957 to 1959. The staking and patenting costs accumulated by October 1960 were \$100,000. Also, \$589,000 in exploration drilling expenditures were made in 1957 and in 1958 to define the ore body. The lands and leases, mine development, equipment, and mine facilities have been described previously. The costs, in thousands of dollars, for equipment, mine facilities, and mine development (shaft and drifts) as of October 1960 are tabulated below:

Lands and leases (staking and patenting)	\$ 99
Mine development (shaft and drifts)	884
Equipment	296
Mine facilities	568
Total	\$1,847

In-situ leach facilities were set up in 1962. The initial capital expenditures by 1962 were \$48,000. During 1962 to 1967 capital expenditures for the in-situ leach facilities accumulated to \$129,000.

For the period 1958 to 1970, concentrate production was sold pursuant to an AEC contract at approximately \$8 per lb except in 1969 and 1970. The commercial market began in the late sixties. Except for the start-up period from 1958 to 1963, the mines were profitable through 1970. Concentrate costs per pound were in the range of \$4 to \$7 per lb.

The feasibility study of the area 2 open pit mine and a concentrator at Shirley Basin was begun in 1968, while the feasibility study of the area 3 open pit mine was begun in 1976. Additional mineral rights were acquired in 1961, 1963, and 1978 for the area 3 open pit mine. The capital costs at year end, in thousands of dollars, are tabulated below for 1971, 1977, and 1981:

	Capital Costs		
Type	1971	1977	1981
Lands and leases	\$ 1,517	\$ 1,584	\$ 1,584
Development	12,923	14,701	16,518
Equipment	9,014	22,256	35,043
Mine facilities	1,714	3,216	6,052
Mill facilities	8,061	9,123	9,999
Townsite	—	643	638
Total	\$33,229	\$51,523	\$69,834

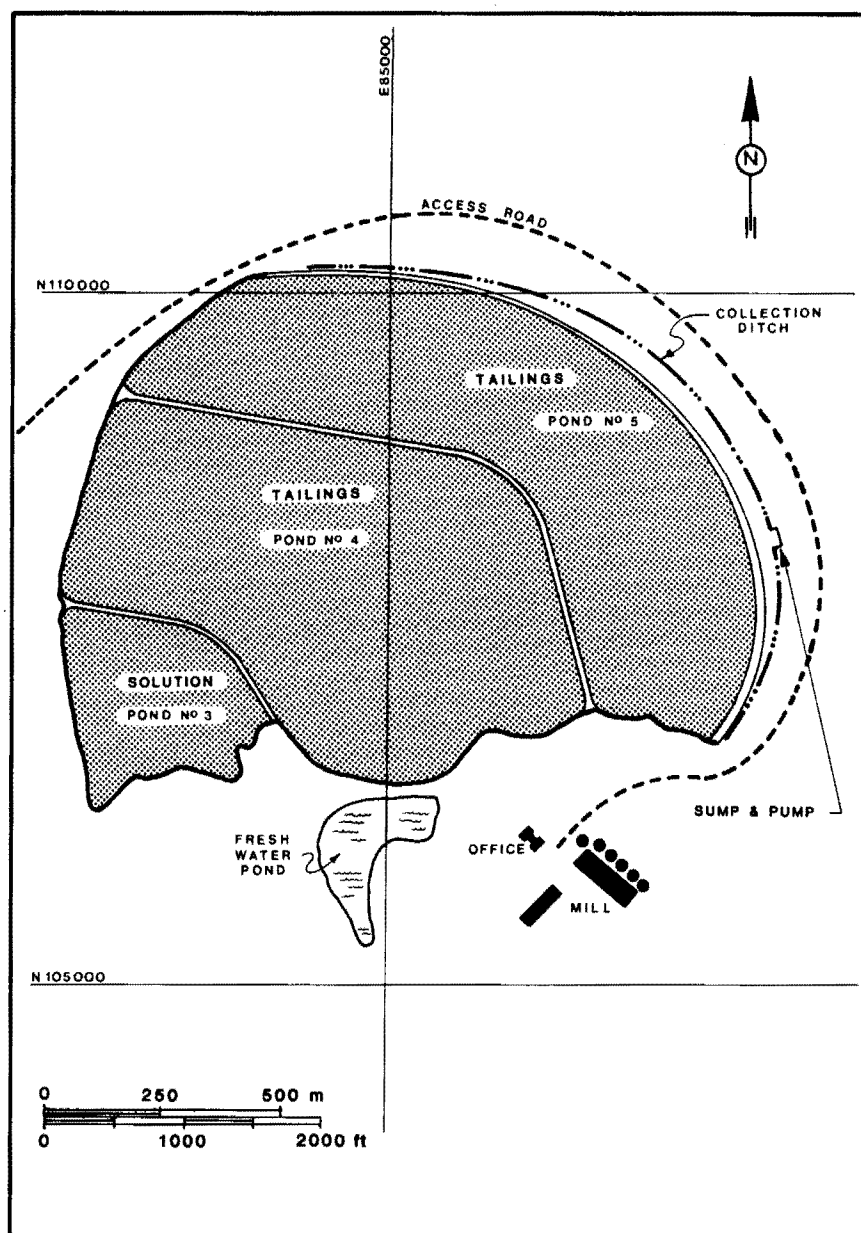

Fig. 5. Plan view of the tailings impoundment, Shirley Basin mine.

The costs of property, plant, and equipment from the inception of Shirley Basin to the end of 1982 are shown in Fig. 6.

Major capital expenditures made after 1963 are listed below:

- 1) In 1968, 12 72.6-t (80-st) scrapers were ordered for mine development operations of the area 2 surface mine.
- 2) In 1968, design work was authorized for a 1088.6-t/d (1200-stpd) mill.
- 3) In 1970, mine development advanced, but development was delayed by pit slope failures and scraper production performance. To compensate, 2 11.5-m³ (15-cu-yd) shovels and 12 108.9-t (120-ton) trucks were ordered.
- 4) In 1971, mill construction was completed and two shovels were placed in operation.
- 5) In 1972, a new scraper fleet replaced the old.

6) In 1977, a 20.6-m³ (27-cu-yd) shovel and six 154.2-t (170-ton) trucks were added to the equipment fleet.

7) In 1975, a cyclone circuit was added to the mill that increased mill capacity from 1088.6 t/d (1200 stpd) to 1633 t/d (1800 stpd).

Following 1977, additional capital expenditures were made:

1. In 1978, a truck shop extension was added to the shop.
 2. In 1978, a new multiple-hearth dryer was constructed in the mill.
 3. In 1978, Spring Creek was diverted to permit area 3 stripping.
 4. In 1979, a hydraulic shovel and three 108.9-t (120-ton) trucks were acquired.
 5. In 1980, six 108.9-t (120-ton) trucks were rebuilt.
- By 1981, the scale of operations had been reduced, a

Fig. 6. Balance of property, plant, and equipment costs, as of year-end (1982), at the Shirley Basin mine.

reflection of the uranium market. The price of U_3O_8 was \$6.05 per lb in 1971 and increased to a maximum of \$43.25 per lb in 1978. On its descent to a low of \$17.50 per lb in 1982, the price of U_3O_8 in mid-1981 was approximately \$25 per lb.

At the start of area 2 in 1971, the concentrate costs including noncash costs were approximately equal to the market price. By 1978, the margin had increased significantly with the concentrate costs at approximately \$17 per lb. Cost of concentrate sales in the 1980s was higher, essentially due to the higher strip ratio of area 3 pits, the reduced scale of

operations, and the accruals for future area 3 final mine reclamation costs. Future final mine reclamation will probably take place post-1990.

9.8 Island Copper Mine

MORTON E. PRATT

Introduction

The Island Copper mine is located adjacent to the Rupert Inlet arm of Quatsino Sound on the north end of Vancouver Island in the Province of British Columbia, Canada (Fig. 1). The residential base for the mine's employees is the town of Port Hardy about 19 km (12 miles) from the mine on the Canadian-Alaskan Inland Waterway some 418 km (260 miles) northwest of Vancouver, British Columbia. The area is served by commercial airlines, bus lines, and trucking lines. The coastal freighter and barge systems that helped build and service the island communities beginning in the 1800s gave way to the trucking industry in 1979 when the national highway system was extended along the island making Port Hardy its western terminus (Figs. 2 and 3).

DISCOVERY AND EXPLORATION

In 1963 the Canadian government released an airborne magnetometer map of the north end of Vancouver Island. The anomalies shown on the map combined with his knowledge of the area prompted Gordon Milbourne, a well-known prospector, to investigate the area. He staked the initial claims in 1965 after finding small quantities of native copper and chalcopryite in outcrops of volcanic rocks north of Francis Lake (sometimes called Bay Lake). He later exposed high-grade chalcopryite in bedrock in two shallow pits in the same area about 1.5 km (0.9 mile) west of the present Island Copper pit. Initially Milbourne, like other explorers in the area, was searching for iron ore, as the island had a record of iron ore deposits. He found no commercial iron but he

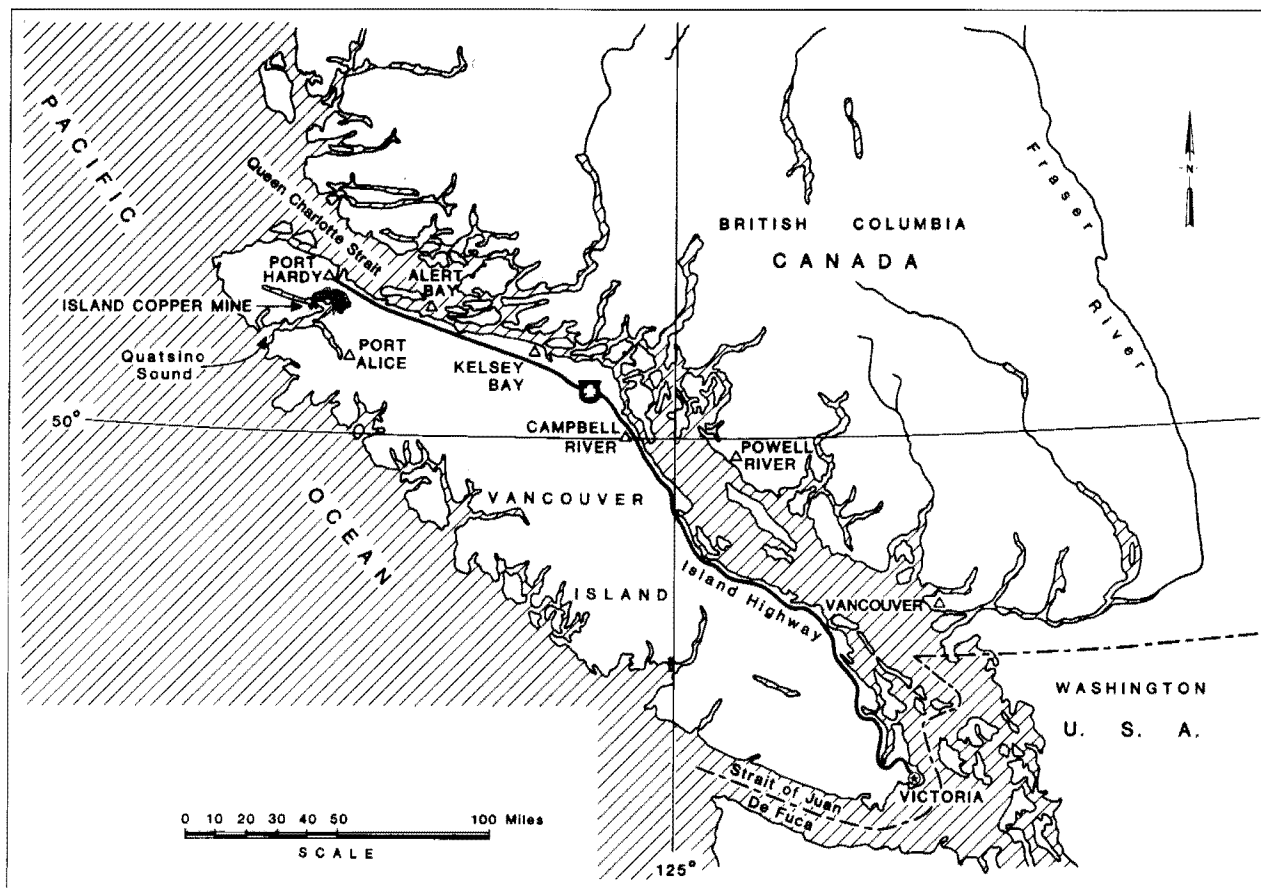

Fig. 2. Location of the Island Copper mine, Port Hardy, Vancouver Island, British Columbia.

had discovered traces of copper and courageously increased his holdings to 112 judiciously placed claims, strategically located over an anomaly that represented the disseminated copper deposit.

In 1966, Milbourne and Utah Construction and Mining Co. signed an option agreement permitting Utah to explore these claims. After initially disappointing diamond-drill results, Utah in 1966 moved away from the original Milbourne discovery site to a second area on which a soil geochemical survey had delineated a large copper anomaly. Ground magnetic surveys and induced polarization surveys were also completed and provided additional useful information in the anomalous area. This anomaly was tested with four shallow, small-diameter diamond drill holes. The results were encouraging and larger diamond drilling equipment was put on the project. In February 1967, a BQ size drill hole, No. 83, intersected 88 m (290 ft) of commercial-grade mineralization. With this discovery the exploration intensity increased. Additional diamond drills were committed to the project and by 1969 the drilling, guided by the soil geochemistry made effective because of the shallow cover over the ore, had delineated 254 Mt (280 million st) of ore at 0.52% copper and 0.017% molybdenum. The ore body was located within an oval-shaped configuration 2438 m (8000 ft) long, 1067 m (3500 ft) wide, and 366 m (1200 ft) thick.

GEOLOGY

The north end of Vancouver Island, north of Rupert and Holberg Inlets, is composed chiefly of Middle Triassic to

Lower Jurassic volcanic and sedimentary rocks of the Vancouver group (Muller, et al., 1974). The group consists mainly of a thick pile of basalt flows, pillows, and breccias overlain by units of limestone; shale and siltstone; argillite; and an upper sequence of bedded and massive tuffs, formation breccias, flows, and minor sediments. These rocks are intruded by Jurassic granitic rocks occurring in a north-west trending zone and are overlain by Cretaceous conglomerates, siltstones, sandstones, and graywackes.

The structure of the area is characterized by block faults and gently dipping, generally undeformed strata offset by complex sets of steep to vertical faults. Regional metamorphism in the area is low- to very low-grade. Some contact-metamorphic aureoles occur where granitic intrusive rocks intersect carbonate sediments.

The Island Copper deposit is in the shape of an inverted U draped over a quartz-feldspar porphyry dike (QFP) intruding pyroclastic volcanic rocks. The dike parallels the regional strike at N70°W, dips 50° to the northeast, and is bowed up longitudinally in the middle while plunging and digitating to the east and west along strike.

The north or hanging wall ore limb occurs in dark to medium green-gray andesite tuffs and QFP, with andesite breccias marginal to the dike. The crest of the ore body extends over the QFP dike and related breccias to the foot-wall ore limb that consists predominantly of intermixed QFP and altered andesite. Rocks in the ore zone are generally highly altered andesite. Additionally, the ore is fractured and moderately to highly silicified.

In the early years of production at Island Copper, ore came predominantly from the andesite on the north or hanging-wall side of the porphyry dike. The ore character will change to greater amounts of porphyritic ore as the pit deepens and more ore comes from the south or footwall side of the dike. It is estimated that as much as 80% of the ore is of the andesite type.

Of the ore minerals, chalcopyrite and molybdenite, 70% are located in the fracture and cleavage planes of the fine-grained highly fractured andesite. The remaining 30% of the sulfide ore mineralization is finely disseminated within the andesite or the porphyry.

Sulfide minerals in order of abundance are pyrite, chalcopyrite, and molybdenite with very minor amounts of bornite, galena, and sphalerite. Gold, silver, and rhenium are present in the ore. Silicates, magnetite, calcite, clays, and minor amounts of the hydrocarbon gilsonite make up the remainder of the host rock.

PROJECT DEVELOPMENT

Engineering and Feasibility

In 1967 Utah Construction and Mining Co.'s San Francisco-based Technical Services Group was assigned to the project to complement Exploration Group activities. The two groups working within their specific expertise proceeded with the evaluation and development of the project. Elements of the evaluation process were:

1) Exploration drilling continued.

2) A shaft was sunk and drifts crosscutting the ore body were driven to obtain bulk ore samples used for metallurgical testing. The metallurgical test work was conducted in Utah's Palo Alto laboratory and in a Utah pilot plant in Cedar City, UT.

3) Contacts with government agencies, both federal and provincial, were developed in order to determine the conditions and regulations that would be applied to a mining project.

4) The socioeconomic aspects, such as employee housing, transportation, schools, stores, and other people-oriented aspects of the development were investigated both for a construction program and for a mining operation.

5) During this period of investigation and before the final financial feasibility was completed, specific technical choices for all of the components of a mining and concentrating operation were studied, tentative choices were made, and the cost of each was estimated. These included: timber removal from the property, mining methods, economic concentrator size, concentrator location, port location, access roads, water supply, electric power supply, waste dump location, and tailings disposal.

6) Product markets for the copper concentrate and for the potential molybdenum concentrate were investigated.

7) The Utah financial policy was to evaluate for project financing. The project would stand on its own financially as a producer of copper concentrate and finally would be totally financed by Utah.

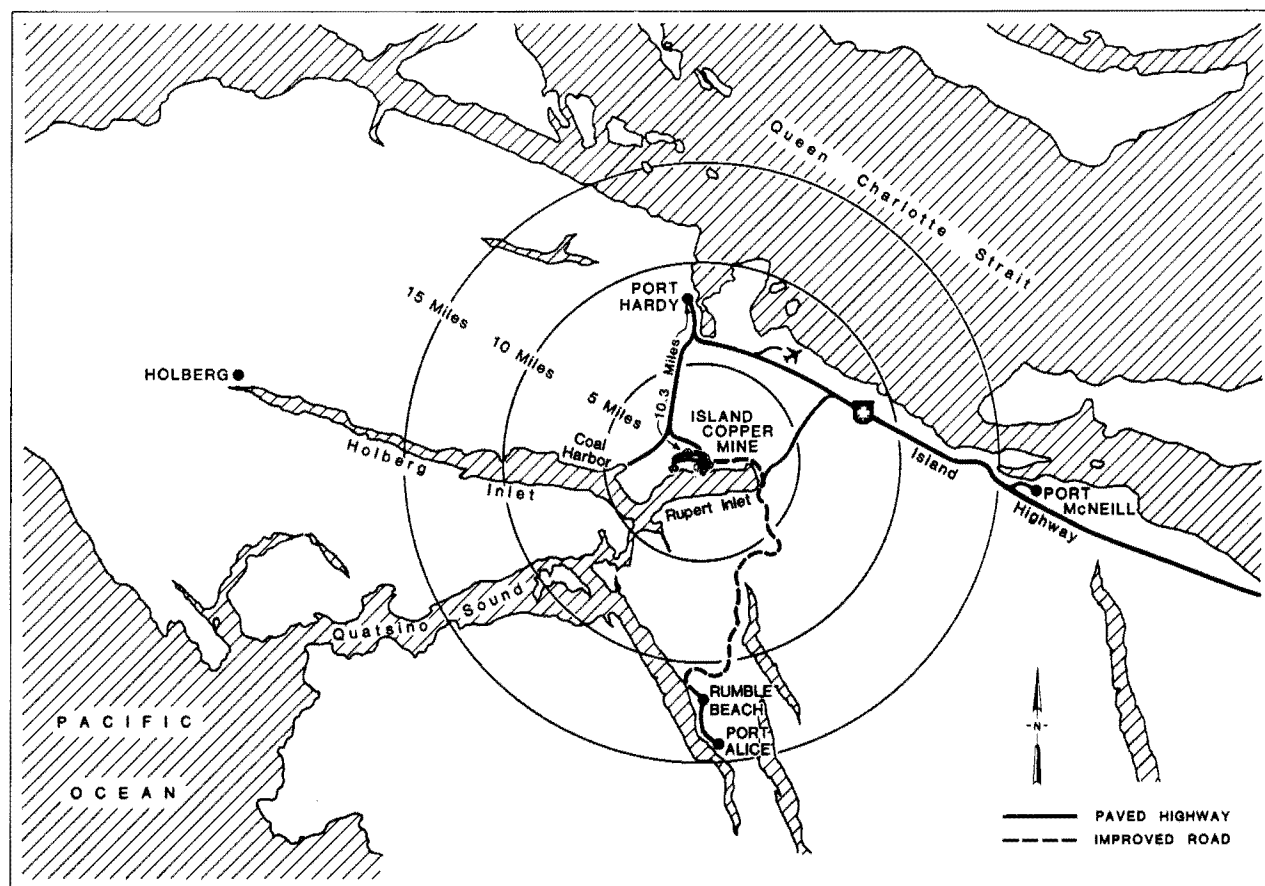

Fig. 3. Port Hardy: Island Copper mine area.

By early 1969 Utah had completed a series of feasibility studies. These evaluations were based on the discounted cash flow method using a 15% after-tax return on investment as the investment guideline. The objective of each evaluation was to:

- 1) Determine if a project based on a given set of assumptions satisfied the DCF investment criteria.
- 2) Determine how sensitive the project's profitability was to changes in various operating conditions and costs.
- 3) Compute the actual dollar cash flows of the project so that the effects on the company's funding arrangements could be ascertained.
- 4) Estimate the project's effects on the company's annual after-tax profits.

Based on the series of evaluations it was determined that:

The copper deposit was economic and not solely a mineral reserve.

A concentrator with a feed capacity of 29.9 kt/d (33,000 stpd) presented the best balanced size choice both financially and operationally.

Following the concentrator size selection, the remainder of the facility would be sized to serve the concentrator.

Mine Planning

At the completion of these assessments the selected design, designated as pit D for identification purposes, was used for final feasibility (Fig. 4). The basic tenets of this design were overall pit slopes of 45° on straight sections, about 34° on convex sections, and 37° for the glacial till overburden.

Ramps at 8% and 30.5 m (100 ft) wide, and 12-m (40-ft) working benches with 10.7-m (35-ft) safety berms spaced at 24-m (80-ft) intervals, completed the major design tenets.

Reserves were 256.7 Mt (283 million st) at 0.522% Cu and 0.029% MoS₃, with an overall stripping ratio of 2.23 t of stripping per tonne of ore. The following reserve Tables 1 and 2 show the distribution of ore and waste in pit D by grades and by bench elevations as estimated early in 1969.

Discussion with the Department of Transport had indicated that the government would approve a well designed waste dump in Rupert Inlet, and haul cycles were estimated for various mine operating periods based upon dumping half of the waste material on land and half into the water of the inlet. A marine dump was financially attractive as it would reduce the amount of lift required for much of the waste. Additionally, Rupert Inlet was up to 76.2 m (250 ft) deep, and the marine dump adjoining the pit would provide for a close large dump. Finally, the dump would increase the size of the rock barrier to be left between the pit and the inlet. Glacial till and swamp mud were excluded as not suitable for the marine dump due to instability and water discoloration by the mud and would be dumped on land.

A drilling and sampling program to determine the vulnerability to seepage of seawater through the barrier area was undertaken and the results indicated that seepage would not become a problem. As a safety measure, the Provincial Inspector of Mines requested a temporary slope on the pit side adjoining the inlet of less than 45% design slope until the pit was below sea level and the barrier wall more thor-

oughly tested and evaluated. This restriction posed no initial problem and will be discussed later in this chapter.

The 29.9 kt/d (33,000-stpd) program called for 9.1 Mt (10 million st) of pre-mine stripping followed by 50.8 Mt (56 million st) of stripping during the first five years of operation distributed as shown in Table 3. Table 4 lists the initial (1969) fleet of mining equipment. Tables 5 and 6 list the current fleet of mining equipment.

CONSTRUCTION

The directors of Utah Construction and Mining Co. approved the expenditure and authorized the start-up of the project in May of 1969.

Construction was started during the summer of 1969 and the first copper concentrates were produced 28 months later in September of 1971. The rain forest was cleared and the

area transformed into an operating open pit mine equipped to feed the newly constructed 29.9 kt/d (33,000-stpd) concentrator. A port was built on Rupert Inlet complete with barge and ship docks. A water system with pumping station on Lake Alice and 16 km (10 miles) of water pipeline to the concentrator was installed. Access roads were built and a housing subdivision was constructed in Port Hardy. The British Columbia Hydro and Power Authority constructed 193 km (120 miles) of 138 kV power transmission line from the Strathcona generating station near Campbell River on Vancouver Island to furnish the mine with electricity. The diesel-powered generating station at Port Hardy did not have the capacity to provide sufficient electrical energy to supply the plant demand of approximately 44 760 kW (60,000 hp).

Because a 64-km (40-mile) gap in the public highway along the island existed between Kelsey Bay and Beaver Cove on Vancouver Island, truck transport for construction material and operating supplies was not practical; therefore, the construction materials and supplies were assembled in a marshalling yard in Vancouver and barged up the Inland Waterway around the north end of Vancouver Island into Quatsino Sound and offloaded on a beachhead at the Rupert Inlet mill site.

The overall design of the project was directed and controlled by Utah's Technical Service Group under C. K. McArthur with detailed design and construction by Fluor-Utah Engineers and Contractors Inc. of Menlo Park, CA. Detailed engineering in Canada was contracted by the H. A. Simmons Co. of Vancouver, BC, operating under Fluor-Utah's supervision.

At the start of construction and to complement the efforts of the San Francisco-based management and design groups, the mine operating group (Utah Mines Ltd.) was established

in Vancouver and individuals moved as required to Port Hardy during the two-year construction period. The group started with a manager, mine superintendent, administrative manager, mill superintendent, chief mine engineer, owners' construction representatives, and office manager, and grew to a full operating crew at the site 28 months later when operation started.

During the two-year period of plant construction, the mine was being prepared for production. The rain forest was logged and stumps removed and burned, streams were relocated, swamps were drained, and roads were built to the areas initially required for stripping and mining. The pre-mine waste stripping program of 9.1 Mt (10 million st) was relatively minor. This was fortunate as the use of the 11.5-m³ (15-cu-yd) electric shovels selected for the project could await the completion of the electric power transmission line from down island, rather than having to install temporary power for a longer pre-mine program. The transmission line project, initially planned for completion in November 1970, was completed and the pit electrified in May 1971, four months before the scheduled start-up. When it became apparent that the initial schedule for pit electrification could not be met, the scope of work for the contractor retained to build the access roads was increased to include the stripping of waste and starting the development of mining faces. After the electricity arrived, the production equipment took over this development program. Also, an unforeseen provincially-imposed requirement for the construction of an emergency mill tailings basin prior to the start of production forced the unscheduled quarrying of approximately 0.9 Mt (1 million st) of waste. Because of tidal action, the quarried waste had to be physically coarse and blocky as it was placed in marine dams used to cordon off a section of the inlet. Unfortunately,

the waste from the scheduled pre-mine stripping was fine and was not suitable for marine dams. Because of this requirement for coarse materials, a part of the truck and shovel hours scheduled for the pre-mine stripping program was diverted to build this tailings basin and the tonnage lost had to be made up after production started. The mining operation was able to cope with these unforeseen requirements and to deliver ore to meet the mill's starting date.

MINING OPERATIONS

General

The Island Copper ore body is mined by open-pit methods. The final pit will be 2438 m (8000 ft) long, 1067 m (3500 ft) wide, and 488 m (1600 ft) deep, extending 378 m (1240 ft) below sea level. It is known that copper mineralization continues below the design depth of the pit and the future economics and technology of copper mining will determine the economic life of the ore body beyond current planning. Table 4 is a list of the equipment purchased to start the mining operation.

The production plan selected and adhered to for the past years has been modestly flexible and capable of producing at the stripping ratio required to keep the mill in ore while providing a reasonable quantity of immediately available ore to be used in the event of a catastrophic failure. Due to the physical configuration of the ore body and the land form over the ore body this planning has resulted in:

- 1) A minor pre-mine stripping program as pointed out previously.
- 2) A buildup to a higher than average stripping ratio in the early years of operation.
- 3) A tapering off in the latter years to a less-than-average stripping ratio.

The development of the pit over the past ten years has resulted in only minor changes in ore locations, minor pit slope changes, and some access design change. The total quantities remain essentially unchanged from the pit D design (Fig. 4).

The Island Copper ore reserves initially were calculated by the polygon method. Over the years, the tons and average grade mined as measured by the blasthole assays have compared closely to the tons and grade predicted by polygons generated by the diamond drill holes and the assays. Ore tons were underestimated by less than 2.5%, the grade overestimated by less than 3.5%, and the contained copper overestimated by about 1%. In 1979 in order to refine this measurement system, a regression of the mean actual polygon grade, using the blasthole grade, for classes of predicted polygon grades showed that the high-grade drill-hole assay assigned to polygons overestimated the actual polygon grade and that assigned low-grade assays underestimate the actual grade. To improve the grade predictions within individual polygons, correction factors derived from the regression curve have been used for the past three years in ore reserve calculations. To date, geostatistical reserve estimation methods such as kriging have been tested at Island Copper but have not been used to generate reserves. The continuity of ore in the deposit is such that reserve estimation errors from using polygons have not been a problem.

In 1978 the design of the road grades was increased from 8 to 10%. This design modification resulted in a minor reduction in the overall amount of stripping required.

After 11 years of operation and experimentation in design and blasting practice, the overall pit slopes vary from 50%

on the north, andesite, and final wall to 40% in the porphyries and the porphyritic mixtures. The steep to vertical faults mentioned in the geologic part of this section exercise degrees of local control over the pit slopes.

The barrier wall between the pit and Rupert Inlet is slightly flatter than the 45% design. An alluvium or till area below sea level was removed and refilled to proper compaction standards. There are no indications of salt water seeping into the pit.

Mining in this rain-forested basin provides unique challenges. First, the ore body and waste rock were overlain by glacial till that ranged in thickness from 4.6 m (15 ft) in the center of the pit to 76.2 m (250 ft) on the east and west ends. Benches are mined to a height of 15.2 m (50 ft) in glacial till and are mined to a 12-m (40-ft) height in rock. The removal of glacial till was efficient and at a high production rate only during the dry season (normally July and August) and occasionally during the winter, if the ground was frozen to a depth that would support the haul trucks. Unfortunately, the normal procedure in till was costly, as the wet till turned to mush under the weight of the trucks or shovels and required a pad of 0.9 to 1.8 m (3 to 6 ft) of shot rock on the mining bench in order to support the shovel and the trucks. The second requirement was to ditch left or right, close to and along the face, to drain the till, and to confine the water to the ditch in order to keep the bench as dry as possible. The extra work required reduced the production rates and forced the rehandling of the shot rock.

Second, the swamps that were scattered over the area were removed with the mining shovels, usually by mining into the swamp from a lower elevation with the shovel operating on a thick rock foundation with water diverted into ditches away from the shovel. Occasionally the mud flow feeding the shovel would be at a rate where the shovel stayed at one spot and dug for hours. More commonly the mud either came too fast or too slowly, which forced the shovel to retreat from the face or caused a delay while the rock pad was advanced. Either event reduced the rate of production.

The andesite used for the shovel pads had to be mined in conjunction with the till or swamp mud as this shot rock was the cheapest shovel pad and surfacing material available. Andesite, the best of the poor road surfacing material available, pulverizes under the heavy weight of the loaded truck's wheels, which results in mud on the roads, at the mining faces, and in the drainage ditches most of the year.

Mine operations, including supporting maintenance work, are continuous and on a schedule of three shifts a day, for seven days a week. Operations in the pit are controlled by a shift supervisor and two principal foremen, one supervises production, and one is assigned to pit services, including pit dewatering, road maintenance, and dump maintenance. Additionally, routine traffic in the pit is supervised from a dispatch office located on high ground at the edge of the pit. This traffic supervisor in the observation post can see all vehicles and equipment in the pit, and dispatch the trucks to the shovels by radio. Additionally, this dispatcher/supervisor acts as a second set of eyes for the shift foremen in preventing accidents and equipment breakdowns as well as the primary assignment of allocating trucks to ensure the most efficient balance of shovels and trucks. Banks of floodlights provide adequate visibility during hours of darkness.

Drilling and Blasting

Drilling is by electric rotary drills. The holes are 251 mm (9 7/8 in.) in diam drilled to grade in glacial till and to 1.2 m (4 ft) below grade in rock. The glacial till could be dug

unshot; however, shovel productivity increased materially when the till was drilled on wide spacing and shot lightly.

The rotary drills used are the Bucyrus-Erie 60Rs and one 45R. The 45R was purchased equipped as a diesel-electric and subsequently converted to full electric. The purpose of the 45R diesel was to provide drilling capacity for the pioneering work with a machine lighter than the 60Rs and with diesel power to permit it to operate in advance of the principal mining areas.

Drill patterns vary according to local rock conditions with detailed engineering and production monitoring to ensure efficiency. The current practice is generally as follows:

Material	Spacing	Powder Factor
Andesite	8.2 x 8.2 m (27 x 27 ft)	0.47 kg/m ³ (0.8 lb/yd ³)
Porphyry	7.6 x 7.6 m (25 x 25 ft)	0.59 kg/m ³ (1.0 lb/yd ³)
Till	9.1 x 9.1 m (30 x 30 ft)	0.30 kg/m ³ (0.5 lb/yd ³)

Initially explosives used were of three types, (1) ANFO in bulk with wet blasthole charges kept dry with plastic waterproof hole liners, (2) packaged water repellent types of ANFO products, and (3) packaged slurries for very wet holes and holes that could not be pumped dry. Since 1978 the only explosive used has been waterproof slurry manufactured by a contractor in a truck-mounted plant at the blasthole and delivered to the blasthole by hose.

Loading

Broken material from the pit is loaded into trucks by P&H or Marion electric shovels equipped with 11.5-m³ (15-cu-yd) buckets. Normally four or six shovels operate to provide the tonnages required.

The original loading shovels were P&H 2100 B mining shovels and now are P&H 2100 BLs and Marion 191M mining shovels with one 2100B left for emergencies and stockpiles. The 11.5-m³ (15-cu-yd) bucket is the standard and normally one shovel will operate with four to six trucks.

Hauling

The ore and waste haul trucks are diesel-powered with final drive by electric motors in each rear wheel. The initial haul truck fleet at the mine utilized the Unit Rig M120 truck, each of 108.9-t (120-ton) nominal capacity equipped with 59.6-m³ (78-cu-yd) capacity boxes. The effective payload for this truck averages 104.3 t (115 st) of ore or 99.8 t (110 st) of waste. In 1974 the fleet was augmented with Unit Rig Mark 36 trucks at a rated capacity of 154.2 t (170 ton) with 83.3 m³ (109-cu-yd) struck box capacity. Since 1979, truck additions have been the Euclid Model R-170 rated at 154.2 t (170-ton) capacity and carrying a 145-t (160-st) payload. The engines used are the General Motors V-12-149-T in the 108.9-t (120-ton) trucks and the General Motors V-16-149-T1 in the 154.2-t (170-st) class trucks. The electric motors in the wheels are the General Electric 772 series in the 108.9 t (120-ton) and the General Electric 776 series in the 154.2-t (170-ton) trucks.

Ore is hauled from the pit to the crusher over a distance of 1.6 to 2.4 km (1 to 1.5 miles), involving a maximum climb of up to 204 m (670 ft) from the bottom operating level 146 m (480 ft) below sea level to the crusher at 58 m (190 ft) above sea level. Haul roads are 36.6 m (120 ft) wide and ramp grades in the pit are 10%. Waste is dumped on land to the north of the pit and into a low-level marine fill to the south of the pit.

High rolling resistance due to the wet and muddy conditions is a serious trucking cost factor at this property. The

rolling resistance on an average haul road during an average wet day at Island Copper is in the order of 2 to 3% higher for a given grade than it would be on a dry desert road or on a frozen road.

Productivity

The 1982 average rates of productivity are as follows:

Mining Rates		
Ore	43.3 kt/d	(47,700 stpd)
Waste	111.4 kt/d	(122,800 stpd)
Total	154.7 kt/d	(170,500 stpd)
Loading Rate		
Shovels	1.5 kt/operating h	(1692 st per operating hr)
Hauling Rates		
Trucks—170T trucks or 170T truck equivalents	276 t/operating h (304 st per operating hr)	
Drilling Rate		
Drills	22 m of penetration per operating hour	(73 ft of penetration per operating hour)

The designed capacity of the plant was a nominal 29.9 kt/d (33,000 stpd) which, considering the estimated 95.76% onstream factor, calculates to 28.7 kt/d (31,600 stpd) on an annual basis. The capacity was increased to 32.7 kt/d (36,000 stpd) in 1973 with the addition of three secondary ball mills. As the techniques of operating the six semiautogenous mills that are the prime grinding tools improved, it became possible to increase the plant throughput and the mine capacity increased accordingly.

Additionally and in response to copper price changes, it became economically attractive to process material in the low-grade category, ores containing between 0.20 or 0.30% copper. With the additional grinding capacity, the practice has been to treat low-grade ore during a copper market recession and higher-grade ore when the market was high. This system, while not the common operating pattern, has best fulfilled Utah's needs. Table 5 gives the average production rates and stripping ratios for the years 1972 through November of 1982.

Production from the pit, originally designed at 101.6 kt/d (112,000 stpd) of ore and waste, was increased to as high as 155.1 kt/d (171,000 stpd) in 1978. At the time of writing, production is at 43.3 kt/d (47,700 stpd) ore and low-grade ore and 111.4 kt/d (122,800 stpd) waste for a total of 154.7 kt/d (170,500 stpd).

The stripping ratio over the 11 year period since start-up has been 2.93 t waste to 1.00 t ore. This ratio is scheduled to decrease in future years to give a final overall ratio of the pit as initially designed of 2.1:1.

Auxiliary Activities

The wet climate and the requirements of pioneering new benches amidst the stumps of a logged-off rain forest have made it necessary to have a larger fleet of auxiliary vehicles than normally would be required for a mine of this size.

The auxiliary fleet includes five graders, three rubber-tired dozers, and large-sized track laying dozers. A front-end loader and 31.8-t (35-ton) class truck loading and hauling group is used for miscellaneous auxiliary work, including mud cleanup and the initial development of benches suitable for the large equipment. For ditching and ditch cleanup a

Gradall and a backhoe are used with the aforementioned auxiliary equipment.

Electrical power is used for the mining shovels, rotary drills, pumps, and pit lights. The pit is supplied from the main transformer station located adjacent to the mill by a conventional power transmission line fed by two 13.2 kV feeders. This transmission line circles the pit and short overhead lines, with the poles on movable bases, feed down the pit walls where needed to 2000-kVA mobile substations located on lowboy trailers within the pit. The circle or ring configuration of the main feed line provides for maximum flexibility in the location of substations and in balancing electrical loads. The mobile transformer stations in the pit convert 13.2-kV main supply to 4160 V for major equipment and to 575 V for auxiliary services. The transformers are moved to serve new working areas and are located near the shovel and drill sites. Electrical cables from the transformers to the mining machines are equipped at both ends with male couplings. The cables are connected through portable junction boxes. This configuration precludes error during cable stringing and the elevated junction boxes keep the couplings out of the mud. The cables are protected in working areas by markers and in road crossovers placed in ground-level rubber crossover channels or on overhead gantries.

Water is collected in the pit by gravity and by pumping diverted to a main sump normally located a level or two above the bottom level of the pit. The main sump, or sumps, have settling areas for mud removal and are equipped with parallel sets of main pumps. The first set is electrically driven and the backup set is powered by diesel engines. The diesel units provide pumping capacity for peak demands, as well as the capability to pump water from the pit during an electric power outage.

The current maximum pump capacity is 0.757 m³/s (12,000 gpm) and is scheduled to be increased to 0.946 m³/s (15,000 gpm). At the present time the water is pumped from the 680 bench sump, 97.5 m (320 ft) below sea level to 3 m (10 ft) above sea level. Water pumped from the pit is initially discharged into a silt settlement basin adjoining Rupert Inlet and from there percolates into the salt water of Rupert Inlet.

Maintenance

The Island Copper maintenance crews are on the schedule of the pit operating crews, i.e., three shifts per day seven days per week for the shift electricians and for the truck maintenance crews. The specialty shops, such as auxiliary equipment, lubrication, tires, field preventive maintenance, small vehicle, component rebuild, welding, and electrical, work two shifts per day seven days per week.

At Coal Harbor the Detroit diesel distributor installed a diesel engine rebuild shop for GM engines in 1971. This local service fulfilled the need for the engine rebuild shop that might be expected in this semi-remote area considering the number of truck diesel engines being operated by the mine. The Caterpillar Tractor Co. dealer established a general maintenance shop in Port Hardy in the late 1970s. Engines are transported to Vancouver for major rebuilding.

Electric wheel motors are rebuilt by the General Electric agent W. A. Stevens Co. in Vancouver or by Island Copper's component rebuild group.

Table 6 delineates the age of the equipment in use and the machine performance. The performance efficiencies were calculated on the following basis and using the following formulae:

- 1) The reporting of hours is on a 24-hr day basis.
- 2) Mechanical Efficiency:

$$\frac{\text{Hours Operated}}{\text{Hours Operated} + \text{Downtime Hours}}$$

- 3) Utilization:

$$\frac{\text{Hours Operated}}{\text{Elapsed Time}} \\ (\text{Hours per Month or Year})$$

- 4) Mechanical Utilization:

$$\frac{\text{Hours Operated} + \text{Downtime Hours}}{\text{Elapsed Time}}$$

Table 7 is a summary giving the distribution of equipment operating costs for a six-month period during 1982. These site- and time-specific costs reflect the use of new equipment on the most arduous work and as such are not a brand endorsement. The practice is to schedule new trucks for the haul from the bottom levels of the pit and the old trucks for the more nearly level hauls. The effect of this preferential scheduling is immediately apparent in operating costs and is also shown in the relatively high mechanical efficiency achieved by old equipment [59.2% for 50,000-hr 108.9-t (120-ton) trucks vs. 67.6% for 15,000-hr 154.2-t (170-ton) trucks as shown in Table 5].

The older equipment when scheduled for fewer hours maintains relatively low costs as shown in Table 6. These older machines are maintained during lulls in the maintenance schedule and components are run longer than could be expected for mainline production equipment.

Table 8 summarizes the capital investment made to bring the Island Copper mine into production. The author has used his judgment in distributing the costs of common facilities between the mine and the concentrator. The components of the mixture of expenditures, such as \$2.5 million for housing when a similar deposit in another location might require no expenditures for housing or more than the Island Copper expenditure, illustrate the variability in capital costs for specific developments.

Table 9 lists the Canadian dollar operating costs for an eight-month period in 1982. In this period of rapidly changing costs they reflect only a point in time and cannot be evenly factored to give future costs. With time, the pit will deepen, the quantity of water to be pumped will increase, and fuel prices change, to mention just three of the many cost elements that will make up future mining costs at the Island Copper Mine.

Table 8. Mine Capital Costs 1969–1970

	Project US\$ 1000s	Mine Dept., US\$ 1000s
Pre-mine development*	15,883	15,883
Townsite, land and houses (half to mine)	2,509	1,255
Mining equipment	11,130	11,130
Camp buildings and facilities (half to mine)*	568	284
Subtotal		28,552
Buildings		
Assay laboratory (half to mine)*	388	194
Maintenance shop	1,158	1,158
Grease building	442	442
Plant warehouse (half to mine)*	263	132
Dock warehouse (half to mine)*	132	66
Office building (half to mine)*	166	83
Change house (75% to mine)*	257	193
Subtotal		2,268
General facilities		
Water supply (10% to mine)*	4,184	418
Electrical system (15% to mine)*	6,710	557
Sanitation and auxiliary equipment (50% to mine)*	258	129
Subtotal		1,104
Grand Total		31,924

* Based on the author's estimate of use by the mine department.

Note: At the start of construction the Canadian dollar was pegged at 93¢ US. When freed to float in 1969, the exchange moved up to around 98¢ for the remainder of the construction period.
